Mr. W. B. Tegetmeier, another well-known authority, gives (*Field*, January 22, 1887, p. 114) the results of a number of experiments on the speed of homing pigeons made under the auspices of the United Counties Flying Club in 1883. The average speed of the winner in eighteen races was 36 miles, and the maximum 55 miles per hour. The greatest distance flown was 309 miles.

The albatross, the largest web-footed bird, measuring sometimes 17 feet from tip to tip of wing, and weighing up to 20 lbs., frequently accompanies ocean steamers from the Cape to Melbourne, a distance of 5,500 knots, without being seen to rest on the way.

An American naturalist, Mr. J. Lancaster, who spent no less than five years on the west coast of Florida ("Problem of the Soaring Bird," *American Naturalist*, 1885, pp. 1055–1162), in order to study the habits of aquatic and other birds which frequent these shores, arrived at the following conclusions, viz.:—

Though all birds move their wings sometimes, many can remain indefinitely in the air, with wings extended and motionless, and either with or without forward movement. This he calls "soaring."

The wing-area of soaring birds varies from 1 to above 2 square feet per lb. of weight.

The larger the wings per lb. of weight the greater the power to soar.

The heavier the bird the steadier his movements.

Soaring birds always face the wind, which, if they do not move forward or downward, must not blow at a less speed than 2 to 5 miles per hour.

Mr. Lancaster specially watched a flock of buzzards about 30 feet above his head, waiting for him to leave the body of a dead porpoise. Their wings were about 8 feet from tip to tip, and their average weight about 6 lbs. During three hours at mid-day, when the wind which they faced was very strong, they flapped their wings about twenty times each. Later, during two hours, when the wind had subsided, they never moved them at all.

Mr. Lancaster timed frigate birds, and found them able to go at the rate of 100 miles per hour, and that on fixed wings; he is of opinion that at all events up to that speed they can fly just as fast as they please. He says, further, that the same birds can live in the air a week at a time, night and day, without touching a roost, and that buzzards, cranes, and gannets can do the same for several hours at a time.

The observed facts relating to the phenomena of flight are still but very imperfectly understood. That a bird should be able to maintain a downward pressure on the air sufficient to counteract the effect of its own weight, and a backward pressure sufficient to force itself forward at such speeds as I have named, seems wonderful enough when it is known that it continuously operates its wings. But that it should be able to do the same without any muscular movement at all is almost incomprehensible. It seems to be an instance of the suspension of the laws of gravity and of the existence of cause without effect, and of effect without cause. It is not a case of flotation, like a balloon, for any bird falls to the earth like a stone when shot. Mr. Lancaster suggests that the bird's own weight is the force which enables him to counteract the effect thereof, but this explanation is, I confess, beyond my comprehension.

It seems to me that for every pound of his weight pressing downwards there must be an equivalent force pressing upwards. This can be produced only by his giving downward motion to the air previously at rest, or by his arresting previous motion of air in an upward direction. The latter alternative involves the supposition that the air-currents which soaring birds face are not, as Mr. Lancaster believes, always horizontal, but must have, to some extent, an upward direction. If a parachute were falling in a current of air which was moving upwards at the same rate as the parachute fell, it would obviously retain its level, yet gravity would be acting. So, if a bird with extended wings were sliding down a stream of air which was tending upwards at the same angle and same velocity, the phenomenon of soaring would be produced.

Weight of Birds in relation to their Bulk.—It is generally believed that birds are lighter, bulk for bulk, than other animals, and that to this lightness they owe, in some degree, their power of flight and of floating on water. To account for this it is said that their bone-cavities are filled with air, and that some, though not even all, flying birds have small air-sacs under the skin. It is clear, however, that displacement of external air by air-filled cavities can only assist aërial floatation to an infinitesimal extent, unless highly heated. Such cavities would, however, help aquatic birds to swim, if situated under the immersed portion of their bodies, which is not always the case.

Some aquatic birds, such as swans, swim with head, neck, wings, tail, and half their bodies out of the water. The specific gravity of fishes and land animals is clearly about the same as water. For, when swimming, they can keep only a small portion of their heads above the surface, and that by continued exertion. Are, then, birds, in the substance of their bodies, less dense than other animals, although also composed of flesh, blood, and bone, and these components in similar proportions and of similar character and texture? If they are, then land animals might have been made lighter in proportion to their bulk or smaller in proportion to their weight than they have been. If they are not, how is it that some of them can swim and float high out of the water?

Having an opportunity recently of inspecting a large wild, or whooper, swan, I ascertained its weight to be 14 lbs. I noticed that the whole of the under-part of the body, which would be immersed when swimming, was covered with feathers and underlined with down to an average depth of not less than 1½ inches, or, when closely pressed, say 1¼ inches. The immersed surface I estimated at 1½ square feet. The weight of water displaced by this feather and down jacket, and the consequent extra buoyancy produced thereby was no less than 9·78 lbs. This would account for two-thirds of the bird's body being out of water when swimming, even if the body were of the same specific gravity as water.

I next procured a freshly-shot wild duck, which weighed 2½ lbs., and placed it in a tank of sea-water. It floated. I found the area of its immersed surface to be 54 square inches, and the average depth of its under-feathers and down to be ¾ inch. The water displaced by this envelope would weigh 1·5 lbs., and would support three-fifths of its entire weight. I then had it denuded of all its feathers and down, and again placed in the tank. It then slowly sank to the bottom.

These experiments, so far as they go, seem to prove conclusively that birds are not lighter, bulk for bulk, than other animals, but, on the other hand, about the same specific gravity, and that their floating power lies entirely in the thick jacket or life-belt with which nature has furnished those, and those only which are intended to swim.

Inasmuch, therefore, as the specific gravity of the actual bodies of all animals appears to be about the same, there is no reason to believe that any could have been constructed of lighter material or to lighter design.

Weight in Relation to their Energy.—But notwithstanding this uniformity of specific gravity, there remains the curious fact that flying birds can exert continuously about three times the horse-power per lb. of weight that man can—and, indeed, about three times what is possible for the horse. This marvellous flow of energy in proportion to weight is probably due to rapidity of limb-action rather than to increase of muscular stress. I have timed sea-gulls and found them to flap their wings two hundred times per minute when flying at about 24 knots per hour, and have estimated eider-ducks, making about 36 knots per hour, to be flapping their wings five hundred times in a minute. I say "estimated," for their movements are too rapid for precise counting. This outpouring of energy, which seems to me to be unequalled in terrestrial animals, is nevertheless maintained by birds for indefinitely long periods of time.

A proportionately increased rate of combustion and renovation of tissue as well as of food-consumption are necessary consequences. The higher temperature of the bodies of birds, as compared with other animals,[1] and the well-known voracity of those which, like sea-birds, are almost continuously on the wing, are circumstances which seem to point to the same conclusion. It is confirmed by what we know of steam and other motors. For instance, if a steamship were so built and proportioned that a ton of coal per hour consumed in the boilers would maintain the pressure at 100 lbs. per square inch and produce 1000 horse-power at the propeller; and then if, without other alteration, firing was slackened until the steam fell to 50 lbs. per square inch and there maintained, it is clear that the horse-power produced would be greatly lessened, and so would the temperature of the steam in the boilers, steam-pipes, and cylinders. Thus, other things being equal, the temperature of the steam would rise and fall with the energy given forth by the mechanism.

The suggestion is that the higher temperature of birds, as compared with other animals, is similarly connected with their superior power of producing and maintaining energetic effort.

Aërial Navigation.

Let us now consider what man has done, and may be able to do, in aërial navigation by aid of contrivances which, as in the case of railway locomotives and ocean steamers, are propelled by a power other than that of his own body.

The scientific world is greatly indebted to Mr. Hiram S. Maxim, of London, for recording, in a clear and readable form, the present position of aëronautic mechanisms.[1] So far, the only contrivances which have been fairly successful are balloons, which, unlike birds, depend on atmospheric displacement for their power of sustaining weight or rising or falling.

In balloon experiments our French neighbours have led the way, from the first attempt of the Montgolfier brothers in 1783. During the last twenty years they have made numerous experiments and substantial improvements. Captain Renard and other officers of the French army have constructed a fish-shaped apparatus, and inflated it with hydrogen. It is driven by an electric motor of 8½ horse-power, and has sufficient buoyancy to carry two aëronauts and all necessary accessories. In fair weather Captain Renard has succeeded in travelling at the rate of 12½ miles per hour, in steering in any direction, and even in returning to his point of departure. The balloon, it is said, always keeps level, and so far there have not been any accidents; but no expedition has been attempted in wet or windy weather.

Except that a more powerful motor, going at a higher speed, might be fitted to such an apparatus, Mr. Maxim thinks that it is as near perfection as is ever likely to be reached by a machine depending on aërial flotation. He proceeds to give an account of some experiments made by Prof. S. P. Langley, of the Smithsonian Institution, Washington, and of others by himself, to ascertain how much power is required to produce artificial flight by means of aëro-planes, after the manner of birds, and whether such power can be obtained without exceeding the weight which it would itself sustain.

He says that heavy birds, with relatively small wings, carry about 150 lbs. per horse-power exerted, and birds such as the albatross and vulture probably about 250 lbs. Prof. Langley, with small slanting planes, was able to carry 250 lbs. per horse-power exerted; and Mr. Maxim, using heavier weights in proportion to plane-area, 133 lbs. per horse-power, and using lighter ones, nearly the same as Prof. Langley.

Mr. Maxim has lately developed his energies to constructing a motor which should meet the requirements of the case, and has succeeded, he says, in producing one: a steam-engine burning naphtha and with atmospheric condenser, with a total weight of 8 lbs. per horse-power. He thinks, however (*Engineer*, January 13, 1893, p. 28), that by using light naphtha and its vapour in the boiler instead of water, as well as in the furnace as fuel, a weight as low as 5 lbs. per horse-power may be reached.

Meanwhile Prof. Langley's ideas have been embodied in an experimental flying-machine, a drawing and description of which will be found in the *Daily Graphic* for July 1, 1893. The body, which resembles that of a bird and is 15 feet long, contains the propelling machinery in duplicate. The wings, which are 40 feet across, are of China silk spread on a tubular framework, stiffened with wire trusses. The boilers use liquid fuel and contain a highly volatile fluid. The capabilities of the machine have not yet been practically tested.

Promising as are the results hitherto obtained, they are as yet far from placing us on a level with birds in power to utilise the atmosphere as a navigating medium. The absolutely necessary power of delicate guiding, in rising, falling, and turning, whatever the direction or force of the wind, has yet to be considered and worked out. What would happen in case of a temporary breakdown of the aëro-plane machinery we shudder to think of.

An important step has been effected by the discovery that parachutes with tubular orifices at the top are comparatively safe appliances for descending to the earth from indefinitely high altitudes. Perhaps it may be arranged that each aëronaut should

be able, at a moment's warning, to gird himself with one of these as with a life-belt on board ship, and so descend in safety, or one or more automatically opening in case of disaster might be fitted to the aëro-plane as a whole.

Eventual Exhaustion of Fuel Supply.

I have still to refer to one other question, the consideration of which must always give rise to very serious thoughts. We have seen that the decisive victories which, in modern times, man has gained over matter and over other animals have been due to his use of power derived from other than animal sources. That power has invariably proceeded from the combustion and the destruction of fuel, the accumulations of which in the earth are necessarily limited.

Mechanical appliances, involving the consumption of fuel, have, for a century at least, been multiplying with alarming rapidity. Our minds have been set mainly on enlarging the uses and conveniences of man, and scarcely at all on economising the great sources of power in nature, which are now for the most part its fuels. Terrible waste of these valuable stores is daily going on in almost every department of use. Once exhausted they can never be replaced. They have been drawn upon to some extent for 1000 years, and extensively for more than 100. Authorities say that another 1000 years will exhaust all the more accessible supplies. But suppose they last 5000 years—what then? Why, then, as far as we can at present see, our only motive-powers will be wind and water and animals, and our only mode of transit, sailing and rowing, driving, cycling, riding, and walking.

Sir Robert Ball has estimated that in not less than 5,000,000 and not more than 10,000,000 years the sun will have become too cold to support life of any kind on this planet. Between the 5000 years when fuel will certainly be exhausted and the 5,000,000 years when all life may be extinguished, there will still be 4,995,000 years when, according to present appearances, man will have to give up his hardly-earned victories over matter and other animals, and the latter will again surpass him, each in its own element, because he has no fuel.

Conclusion.

Leaving to our posterity these more remote troubles, we may, I think, justly draw from the entire discussion the conclusion that we have still a great deal to learn from mechanisms as they exist in nature. Great as have been the achievements of man since he first began to study mechanical science, with a view to directing the great sources of power in nature for his own use and convenience, the entire field of research is by no means yet fully exhausted. We must continue to study the same science with undiminished ardour. In so doing we shall do well to bear in mind that success can be achieved only by the patient, accurate, and conscientious observation of the great facts of nature, which are equally open to us all and waiting for our attention; and by drawing correct inferences therefrom, and by applying such inferences correctly to the fulfilment of the future needs and destiny of our race.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY ROBERT MUNRO, M.A., M.D., F.R.S.E., PRESIDENT OF THE SECTION.

THE science of anthropology, in its widest sense, embraces all the materials bearing on the origin and history of mankind. These materials are so comprehensive and diversified, both in their character and methods of study, that they become necessarily grouped into a number of subordinate departments. From a bird's-eye point of view, however, one marked line of demarcation separates them into two great divisions, according as they relate to the structure and functions of man's body, or to the works he has produced—a classification well defined by the words *anthropology* and *archæology*. The former, in its limited acceptation, deals more particularly with the development of man—his physical peculiarities, racial distinctions, linguistic manifestations, mental endowments, and, in short, every morphological or mental modification he has undergone amidst the ever-changing phenomena of his environments. The latter, on the other hand, takes cognisance of man merely as a handicraftsman. During his long journey in past time he has left behind him, scattered on the highways and byways of primeval life, numerous traces of his ways, his works, his culture, and his civilisation, all of which fall to be collected, sorted, and interpreted by the skilled archæologist. In their general aspects and relationship to each other most of the leading subjects in both these branches of the science have already been expounded, in the presidential addresses of my predecessors, by men so distinguished in their respective departments that they have left little to be said by anyone who attempts to follow in their footsteps. There is, however, one phase in the progressive career of man which has not hitherto been so fully illustrated as the subject appears to me to merit. I refer to the direct and collateral advantages which the erect position has conferred on him; and to this I will now briefly direct your attention, concentrating my observations successively on the following propositions:—

(1) The mechanical and physical advantages of the erect position.

(2) The differentiation of the limbs into hands and feet.

(3) The relation between the more perfect condition of these organs and the development of the brain.

In the process of organic evolution it would almost appear as if nature acted on teleological principles, because many of her products exhibit structures which combine the most perfect adaptation of means to ends along with the greatest economy of materials. This is well exemplified in some of the structural details of the organs of locomotion in which many of the so-called mechanical powers may be seen in actual use. The primary object of locomotion was to enable the organism to seek its food over a larger area than was attainable by a fixed position. The acquisition of this power was manifestly so advantageous to animal life that the principles by which it could be effected became important factors in natural selection. I need not here dwell on the various methods by which this has been accomplished in the lower forms of life, but proceed at once to point out that in the higher vertebrates the problem resolved itself into the well-known mechanism of four movable limbs, capable of supporting and transporting the animal. As these quadrupedal animals became more highly differentiated, in virtue of the necessities of the struggle for life and the different and ever-varying conditions of their surroundings, it followed that the limbs became also modified so as to make them suitable, not only for locomotion in various circumstances, but also useful to the animal economy in other ways. Hence they were subjected to an endless variety of secondary influences, which finally adapted them for such diverse purposes as swimming, flying, climbing, grasping, &c. The anterior limbs, owing to their proximity to the head, were more frequently selected for such transformations as may be seen, for instance, in the wings of a bird. But whatever modifications the fore limbs may have undergone, no animal, with the exception of man, has ever succeeded in divesting them altogether of their primary function. This exceptional result was due to the erect position, which necessitated a complete division of labour as regards the functions of the limbs—the two anterior being entirely restricted to manipulative and prehensile purposes, and the two posterior exclusively devoted to locomotion. Coincident with this notable specialisation of their function a new field for advancement was opened up to man, in which intelligence and mechanical skill became the leading factors in his further development.

Man is thus distinguished from all other animals by the fact that, in the normal position of walking or running, he carries his body upright, *i.e.* with the axis of the vertebral column perpendicular, instead of horizontal or oblique. In this position all its parts are so arranged as to require a minimum amount of exertion in the performance of their functions. If any of the other higher vertebrates should ever assume an erect attitude it can only be maintained temporarily, and its maintenance involves an additional expenditure of force. In a certain sense a bird may be looked upon as a biped, but there is this distinction to be drawn between it and man, viz. that the former has not only its body balanced obliquely on its two legs, but also its fore limbs converted into special organs for motion in the air. The anthropoid apes hold an intermediate position, and so carry their body in a semi-erect attitude. But this shortcoming in reaching the perfectly upright position, however slight it may be in some of these animals, represents a wide gap which can only be fully appreciated by a careful study of the physiological and psychological phenomena manifested in their respective life-functions.

Everyone acquainted with the ordinary operations of daily life knows how much labour can be saved by attention to the mere mechanical principles involved in their execution. In carrying a heavy load the great object is to adjust it so that its centre of gravity comes as nearly as possible to the vertical axis of the body, as otherwise force is uselessly expended in the effort to keep the entire moving mass in stable equilibrium—a principle well exemplified by the Italian peasant girl when she poises her basket of oranges on her head. Once upon a time a powerful waterman, accustomed to use buckets double the size of those of his fellow-watermen, had the misfortune to have one of them broken. As he could not, then and there, get another bucket to match the remaining one, and wishing to make the best possible use of the appliances at hand, he replaced the broken vessel by one half its size. He then filled both with water and attempted to carry them, as formerly, attached to a yoke, one on each side of him. But to his astonishment this arrangement would not work. The yoke became uneven, and the effort to keep it balanced on his shoulders was so troublesome that he could not proceed. This emergency led to serious reflection, but, after some experimental trials, he ascertained that, by merely making the arm of the yoke on which the small bucket was suspended double the length of the other, he could carry both buckets without inconvenience.

But let me take one other illustration. Suppose that two burglars have concocted a plan to rob a richly-stored mansion by getting access to its rooms through the windows of an upper story. In order to carry out this design they secure a ladder, easily transported by the two together though too heavy for one. So, bearing the ladder between them one at each end, they come to the house. After a considerable amount of exertion they succeed in placing the ladder in an upright position against the wall, and then one of the men mounts its steps and enters the house. The man left outside soon realised that, once the ladder was balanced perpendicularly, he himself could then easily control it. Moreover, he made the discovery that by resting its weight on each leg alternately, he could gradually shift its position from one window to another. Thus there was no interruption or limit to the extent of their depredations. Experience quickened their perceptions, and ultimately they became adepts in their respective departments—the one in the art of moving the ladder, and the other in the science of the nimble-fingered gentry. The division of labour thus practised by these two men accurately represents what the attainment of the erect attitude has accomplished for man by setting free his upper limbs from any further participation in the locomotion of his body.

The continued maintenance of this unique position necessitated great changes in the general structure of the body. The solution of the problem involved the turning of the ordinary quadruped a quarter of a circle in the vertical plane, thus placing the axis of the spine perpendicular, and consequently in line with the direction of the posterior limbs; and to effect this the osseous walls of the pelvis underwent certain modifications, so as to bear the additional strain put upon them. Stability was given to the trunk in its new position by the development of special groups of muscles, whose powerful and combined actions render to the movements of the human body their characteristic freedom and gracefulness. The lower limbs were placed as widely apart as possible at their juncture with the pelvis, and the thigh- and leg-bones were lengthened and strengthened so as to be capable of supporting the entire weight of the body and of transporting it with due efficiency when required. The spinal column assumed its well-known curves, and the skull, which formerly had to be supported by a powerful muscle attached to the spinous processes of the cervical vertebræ (*ligamentum nuchæ*), moved backwards until it became nearly equipoised on the top of the vertebral column. The upper limbs, instead of taking part in their original function of locomotion, were now themselves carried as flail-like appendages, in order to give them as much freedom and range of action as possible. The shoulder-blades receded to the posterior aspect of the trunk, having their axes at right angles to that of the spine. Further, like the haunch-bones, they underwent certain modifications, so as to afford points of attachment to the muscles required in the complex movements of the arms. In the pendulous position each arm has its axis at right angles to that of the shoulder, but by a common muscular effort the two axes can be readily brought into line. The elbow-joint became capable of performing the movements of complete extension, flexion, pronation, and supination—in which respects the upper limb of man is differentiated from that of all other vertebrates.

But it is in the distal extremities of the limbs that the most remarkable anatomical changes have to be noted. The foot is virtually a tripod, the heel and the ball of the great toe being the terminal ends of an arch, while the four outer digital columns group themselves together to form the third, or steadying, point. The outer toes thus play but a subordinate part in locomotion, and, as their prehensile function is no longer of use, they may be said to be fast approaching to the condition of rudimentary organs. The three osseous prominences which form this tripod are each covered with a soft elastic pad, which both facilitates progression and acts as a buffer for deadening any possible shock which might arise in the course of running or leaping. The chief movement in the act of progression is performed by an enormously developed group of muscles known as the calf of the leg, so characteristic of man. The walker is thereby enabled to use the heel and the ball of the great toe as successive fulcrums from which the forward spring is made, the action being greatly facilitated by that of the trunk muscles in simultaneously bending the body forwards. The human foot is thus admirably adapted to be both a pillar for supporting the weight of the body, and a lever for mechanically impelling it forwards. Hence the amount of energy expended in progression is reduced to a minimum, and when estimated proportionally to the size of the body it is believed to be considerably less than that requisite for the corresponding act in quadrupeds.

The anatomical changes effected in the extremity of the upper limb are equally radical, but of a totally different character and scope. Here we have to contemplate the transformation of the same homologous parts into an apparatus for performing a series of prehensile actions of the most intricate character, but among which neither locomotion nor support of the body forms any part whatever. This apparatus is the human hand, the most complete and perfect mechanical organ nature has yet produced. The fingers have become highly developed, and can be opposed singly or in groups to the thumb, so as to form a hook, a clasp, or a pair of pincers; and the palm can be made into a cup-shaped hollow, capable of grasping a sphere. Nor is there any limit to the direction in which many of these manipulations can be performed without any movement of the rest of the body. For example, a pencil held by the thumb and the two fore fingers, as in the act of writing, can be placed in all the directions of space by a mere act of volition.

The position of such a perfect piece of mechanism at the extremity of a movable arm attached to the upper part of the trunk, gives to man a superiority in attack and defence over all other animals, on the same principle as a soldier finds it advantageous to fight from higher ground. Moreover, he possesses the power to perform a variety of quick movements, and to assume attitudes and positions eminently adapted for the exercise of that manipulative skill with which he counteracts superior brute force of many of his antagonists. He can readily balance his body on one or both legs, can turn on his heels as if they were pivots, and can prostrate himself comfortably in the prone or supine positions. As the centre of gravity of the whole body is nearly in line with the spinal axis, stable equilibrium is easily maintained by the lumbar muscles. Altogether we have in his physical constitution a combination of structures and functions sufficiently unique in its *tout ensemble* to place man in a category by himself. But at the same time we must not forget that all his morphological peculiarities have been brought about without the destruction of any of the primary and typical homologies common to all the higher vertebrates.

Turning now to the brain, the undoubted organ of the mind, we find in its intellectual and psychical manifestations, a class of phenomena which gives to man's life-functions their most remarkable character. However difficult it may be for our limited understanding to comprehend the nature of conscious sensation, we are forced to the conclusion that the act invariably takes place through the instrumentality of a few nerve-cells, whose functional activity requires to be renovated in precisely the same manner as the muscular force expended in walking. The aggregation of such cells into ganglia and nerves, by means of which reflex action, consciousness, and a variety of psychical phenomena take place, is found to permeate, in a greater or less degree, the whole of the organic world. In the higher vertebrates the seat of these manifestations is almost exclusively confined to an enormous collection of brain substance placed at the upper end of the vertebral column, and encased in a complete osseous covering called the skull. We learn from numerous experimental researches, carried out by physiologists in recent years, that the brain is a dual organ, consisting of a double series of distinct ganglia and connected to some extent by a complex system of nervous tissues, not only with each other, but with the central seat of consciousness and volition. But the difficulty of determining the nature of its functions, and the *modus operandi* of its psychological manifestations, is so great that I must pass over this part of the subject very lightly indeed. The conditions of ordinary reflex-action require that a group of muscles, by means of which a particular bodily movement is effected, shall be connected with its co-ordinating ganglion by an afferent and an efferent system of nerves. Impressions from without are conveyed by the former, or sensory nerves, to the central ganglion, from which an impulse is retransmitted by the motor nerves and sets in operation the muscular force for producing the required movement. But this efferent message is, in many cases, absolutely controlled by volition, and not only can it prevent the muscular action from taking place, but it can effect a similar movement, *de novo*, without the direct intervention of external impressions at all. Now it has been proved experimentally that the volitional stimulus, which regulates the various movements of the body, starts from definite portions of the brain according to the different results to be produced. This localisation of brain functions, though still far from being thoroughly understood, comes very appropriately into use in this inquiry. From it we learn that the homology which characterises the structural elements of the bodies of animals extends also to the component parts of their respective brains. The law which differentiates animals according to the greater specialisation of the functions of their various organs has therefore its counterpart in the brain, and we naturally expect an increase of brain substance in every case in which the functional activity of a specific organ is extended. Thus the act of stitching with a needle and thread, an act beyond the mental and physical capacity of any animal but man, would entail a certain increase of brain substance, simply in obedience to the great complexity of the movements involved in its execution, over and above that which may be supposed to be due to the intellectual and reasoning faculties which invented it.

That man's brain and his intelligence are correlated to each other is a fact too axiomatic to require any demonstration; nor can it be doubted that the relationship between them is of the nature of cause and effect. But to maintain that the amount of the latter is directly proportional to the size of the former is rather straining the laws of legitimate inference. In drawing any general conclusion of this nature from the bulk of brain substance, there are some modifying influences which cannot be disregarded, such, for example, as the amount of cranial circulation and the quality of the brain cells. But the determination of this point is not the exact problem with which the evolutionist is primarily concerned. To him the real crux in the inquiry is to account for the evolution of man's comparatively large brain under the influence of existing cosmic forces. After duly considering this problem, and casting about for a possible explanation, I have come to the conclusion that not only is it the result of natural laws, but that one of the main factors in its production was the conversion of the upper limbs into true hands. From the first moment that man recognised the advantage of using a club or a stone in attacking his prey or defending himself from his enemies, the direct incentives to a higher brain development came into existence. He would soon learn by experience that a particular form of club or stone was more suitable for his purposes; and if the desiderated object were not to be found among the natural materials around him, he would proceed to manufacture it. Certain kinds of stones would be readily recognised as better adapted for cutting purposes than others, and he would select his materials accordingly. If these were to be found only in a special locality, he would visit that locality whenever the prised material was needed. Nor would it be an unwarrantable stretch of imagination to suppose that the circumstances would lead him to lay up a store for future use. These simple acts of intelligence assume little more than may be seen in the actions of many of the lower animals. Consciousness of his power to make and to wield a weapon was a new departure in the career of man, and every repetition of such acts became an effective and ever-accumulating training force. What a memorable event in the history of humanity was the manufacture of the first sharp stone implement! Our sapient ancestor, who first used a spear tipped with a sharp flint, became possessed of an irresistible power over his fellow men. The invention of the bow and arrow may be paralleled with the discovery of gunpowder and the use of cannon, both of which revolutionised the principles of warfare in their respective ages. The art of making fire had a greater influence on human civilisation than the modern discovery of electricity. The first boat was in all probability a log—an idea which might have been suggested by the sight of an animal clinging to a floating piece of wood carried away by a flood. To scoop this log into a hollow boat was an afterthought. The successive increments of knowledge by which a single-tree canoe has been transformed into a first-class Atlantic liner are scattered through the unwritten and written annals of many ages. In his expeditions for hunting, fishing, fruit-gathering, &c., primitive man's acquaintance with the mechanical powers of nature would be gradually extended, and *pari passu* with the increasing range of his knowledge there would be a corresponding development in his reasoning faculties. Natural phenomena suggested reflections as to their causes and effects, and so by degrees they were brought into the category of law and order. Particular sounds would be used to represent specific objects, and these would become the first rudiments of language. Thus each generalisation when added to his previous little stock of knowledge widened the basis of his intellectual powers, and as the process progressed man would acquire some notion of the abstract ideas of space, time, motion, force, number, &c.; and continuous thought and reasoning would ultimately become habitual to him. All these mental operations could only take place through the medium of additional nerve cells, and hence the brain gradually became more bulky and more complex in its structure. Thus the functions of the hand and of the brain have been correlated in a most remarkable manner. Whether the mechanical skill of the hand preceded the greater intelligence of the brain, or *vice versa*, I will not pretend to say. But between the two there must have been a constant interchange of gifts. According to Sir C. Bell, "the hand supplies all instruments, and by its correspondence with the intellect gives him universal dominion." ("The Hand," &c. "Bridgewater Treatise," p. 38.)

That mind, in its higher psychical manifestations, has sometimes been looked upon as a spiritual essence which can exist separately from its material basis need not be wondered at when we consider how the pleasing abstractions of the poet, or the fascinating creations of the novelist, roll out, as it were, from a hidden cavern without the slightest symptom of physical action. It is this marvellous power of gathering and combining ideas, previously derived through the ordinary senses, which gives a *primâ facie* appearance of having here to deal with a force exterior to the brain itself. But indeed it is questionable if such psychological phenomena are really represented by special organic equivalents. May they not be due rather to the power of volitional reflection which summons them from the materials stored up by the various localised portions into which the brain is divided? From this point of view there may be many phases of pure cerebration which, though not the result of direct natural selection, have nevertheless as natural and physical an origin as conscious sensation. Hence imagination, conception, idealisation, the moral faculties, &c., may be compared to parasites which live at the expense of their neighbours. After all the greatest mystery of life lies in the simple acts of conscious sensation, and not in the higher mental combinations into which they enter. The highest products of intellectuality are nothing more than the transformation of previously existing energy, and it is the power to utilise it that alone finds its special organic equivalent in the brain.

But this brings us on controversial ground of the highest importance. Prof. Huxley thus expresses his views on the phase of the argument now at issue:—

"I have endeavoured to show that no absolute structural line of demarcation, wider than that between the animals which immediately succeed us in the scale, can be drawn between the animal world and ourselves; and I may add the expression of my belief that the attempt to draw psychical distinction is equally futile, and that even the highest faculties of feeling and of intellect begin to germinate in lower forms of life." ("Evidences as to Man's Place in Nature," p. 109.)

On the other hand, Mr. Alfred R. Wallace, who holds such a distinguished position in this special field of research, has promulgated a most remarkable theory. This careful investigator, an original discoverer of the laws of natural selection, and a powerful advocate of their adequacy to bring about the evolution of the entire organic world, even including man up to a certain stage, believes that the cosmic forces are insufficient to account for the development of man in his civilised capacity. "Natural selection," he writes, "could only have endowed savage man with a brain a few degrees superior to that of an ape, whereas he actually possesses one very little inferior to that of a philosopher." This deficiency in the organic forces of nature he essays to supply by calling in the guiding influence of a "superior intelligence." In defending this hypothesis from hostile criticism he explains that by "superior intelligence" he means some intelligence higher than the "modern cultivated mind," something intermediate between it and Deity. But as this is a pure supposition, unsupported by any evidence, and merely a matter of personal belief, it is unnecessary to discuss it further. I would just, *en passant*, ask Mr. Wallace why he dispenses with this "higher intelligence" in the early stages of man's evolution, and finds its assistance only requisite to give the final touches to humanity.

In dealing with the detailed objections raised by Mr. Wallace against the theory of natural selection as applied to man, we are, however, strictly within the sphere of legitimate argument; and evolutionists are fairly called upon to meet them. As his own theory is founded on the supposed failure of natural selection to explain certain specified peculiarities in the life of man, it is clear that if these difficulties can be removed, *cadit quæstio*. It is only one of his objections, however, that comes within the scope of my present inquiry, viz. that which is founded on the supposed "surplusage" of brain power in savage and prehistoric races.

In comparing the brains of the anthropoid apes and man Mr. Wallace adopts the following numbers to represent their proportional average capacities, viz. anthropoid apes 10, savages 26, and civilised man 32—numbers to which there can be no objection, as they are based on data sufficiently accurate for the requirements of this discussion. In commenting on the mental ability displayed in actual life by the recipients of these various brains, he states that savage man has "in an undeveloped state faculties which he never requires to use," and that his brain is much beyond his actual requirements in daily life. He concludes his argument thus:—"We see, then, that whether we compare the savage with the higher developments of man, or with the brutes around him, we are alike driven to the conclusion that in his large and well-developed brain he possesses an organ quite disproportionate to his actual requirements—an organ that seems prepared in advance, only to be fully utilised as he progresses in civilisation. A brain one half larger than that of the gorilla would, according to the evidence before us, fully have sufficed for the limited mental development of the savage; and we must therefore admit that the large brain he actually possesses could never have been solely developed by any of those laws of evolution whose essence is that they lead to a degree of organisation exactly proportionate to the wants of each species, never beyond those wants; that no preparation can be made for the future development of the race; that one part of the body can never increase in size or complexity, except in strict co-ordination to the pressing wants of the whole. The brain of prehistoric and of savage man seems to me to prove the existence of some power distinct from that which has guided the development of the lower animals through their ever-varying forms of being." ("Natural Selection," &c. 1891, p. 193.)

With regard to the closing sentence of the above quotation, let me observe that the cosmic forces, under which the lower animals have been produced by means of natural selection, do not disclose, either in their individual or collective capacity, any guiding power in the sense of a sentient influence, and I believe that the "distinct power" which the author summons to his aid, apparently from the "vasty deep," to account for the higher development of humanity is nothing more than the gradually acquired product of the reasoning faculties themselves. Not that, for this reason, it is to be reckoned less genuine and less powerful in its operations than if it had emanated from an outside source. The reasoning power displayed by man is virtually a higher intelligence, and, ever since its appearance on the field of organic life, it has, to a certain extent, superseded the laws of natural selection. Physical science has made us acquainted with the fact that two or three simple bodies will sometimes combine chemically so as to produce a new substance, having properties totally different from those of either constituents in a state of disunion. Somethin analogous to this has taken place in the development of man' capacity for reasoning by induction. Its primary elements, whic are also those of natural selection, are conscious sensation, heredity and a few other properties of organic matter, elements whic are common, in a more or less degree, to all living things. A soon as the sequence of natural phenomena attracted the at tention of man, and his intelligence reached the stage of con secutive reasoning on the invariableness of certain effects fro given causes, this new power came into existence; and its opera tions are, apparently, so different from those of its componen elements that they can hardly be recognised as the offspring o natural forces at all. Its application to the adjustment of hi physical environments has ever since been one of the mos powerful factors, not only in the development of humanity, bu in altering the conditions and life-functions of many membe of the animal and vegetable kingdoms.

I have already pointed out that the brain can no longer b regarded as a single organ, but rather as a series of organs con nected by bonds of union—like so many departments in Government office in telephonic communication—all, howeve performing special and separate functions. When, therefor we attempt to compare the brain capacity of one animal wi that of another, with the view of ascertaining the quality their respective mental manifestations, we must first determin what are the exact homologous parts that are comparable. T draw any such inference from a comparison of two brains, b simply weighing or measuring the whole mass of each, woul be manifestly of no scientific value. For example, in the brai of a savage the portion representing highly skilled moto energies might be very much larger, while the portion represen ing logical power might be smaller, than the correspondin parts in the brain of a philosopher. But should these in equalities of development be such as to balance each other, th weight of the two organs would be equal. In this case what coul be the value of any inference as to the character of their menta endowments? Equal-sized brains do not display equivalen nor indeed analogous, results. To postulate such a doctrine woul be as irrational as to maintain that the walking capacities different persons are directly proportional to the weight of the bodies. Similar remarks are equally applicable to the skul of prehistoric races, as it would appear that evolution had don the major part of its work in brain development long befor the days of neolithic civilisation. Huxley's well-known de scription of the Engis skull—"a fair average skull, which migh have belonged to a philosopher, or might have contained th thoughtless brains of a savage"—goes far to settle the questio from its anatomical point of view. Until localisation of brai functions makes greater progress it is, therefore, futile to specu late to any great extent on the relative sizes of the skulls different races either in present or prehistoric times.

But there is another aspect of the question which militate against Mr. Wallace's hypothesis, viz. the probability th many of the present tribes of savages are, in point of civilisa tion, in a more degenerate condition than their forefathers wh acquired originally higher mental qualities under natural selec tion. There must surely be some foundation of truth in th widely-spread tradition of the fall of man. And, if such i the case, we naturally expect to find some stray races with in herited brains of greater capacity than their needs, in more de generate circumstances, may require. An exact equivalent t this may be seen in the feeble intellectuality of many of th peasants and lower classes among the civilised nations of moder times. Yet a youth born of such parents, if educated, ofte becomes a distinguished philosopher. It is well known that an organ ceases to perform its functional work it has a ten dency to deteriorate and ultimately to disappear altogether But from experience we know that it takes a long time for th effects of disuse to become manifest. It is this persistency tha accounts for a number of rudimentary organs, still to be me with in the human body, whose functional activity could onl have been exercised ages before man became differentiated fro the lower animals. Such facts give some support to the sug gestion, previously made, that philosophy, as such, has n specially localised portion in the brain. Its function is merel to direct the current of mental forces already existing.

But, again, Mr. Wallace's argument involves the assumption tha the unnecessarily large brain of the savage had been constructed o teleological principles for the sole purpose of philosophising. M opinion is that the greater portion of this so-called surplusage the organic representative of the energy expended in the exercise of the enormous complexity of human actions, as displayed in the movements of his body and in the skilful manipulations necessary to the manufacture of implements, weapons, clothing, &c. All such actions have to be represented by a larger bulk of brain matter than is required for the most profound philosophical speculations. The kind of intelligence evinced by savages, however low their position in the scale of civilisation may be, is different from, and incomparably greater than, that manifested by the most advanced of the lower animals. To me it is much more rational to suppose that the development of the large brain of man corresponded, *pari passu*, with that of his characteristic physical attributes, more especially those consequent on the attainment of the upright position. That these attributes were acquired exclusively through the instrumentality of the cosmic forces was, as the following quotation will show, the opinion of Mr. Darwin:—"We must remember that nearly all the other and more important differences between man and quadrumana are manifestly adaptive in their nature, and relate chiefly to the erect position of man; such as the structure of his hand, foot, and pelvis, the curvature of his spine, and the position of his head." ("Descent of Man," p. 149.) Mr. Wallace, however, considers the feet and hands of man "as difficulties on the theory of natural selection." "How," he exclaims, "can we conceive that early man, *as an animal*, gained anything by purely erect locomotion? Again, the hand of man contains latent capacities and powers which are unused by savages, and must have been even less used by palæolithic man and his still ruder predecessors. It has all the appearance of an organ prepared for the use of civilised man, and one which was required to render civilisation possible." ("Natural Selection," p. 198.) But here again this acute observer diverges into his favourite by-path, and introduces a "higher intelligence" to bridge over his difficulties.

We have now reached a stage in this inquiry when a number of questions of a more or less speculative character fall to be considered. On the supposition that, at the start, the evolution of the hand of man was synchronous with the higher development of his reasoning faculties, it is but natural to ask where, when, and in what precise circumstances this remarkable coalition took place. I would not, however, be justified in taking up your time now in discussing these questions in detail; not because I think the materials for their solution are unattainable, but because, in the present state of our knowledge, they are too conjectural to be of scientific value. In the dim retrospective vista which veils these materials from our cognisance I can only see a few faint landmarks. All the osseous remains of man which have hitherto been collected and examined point to the fact that, during the larger portion of the quaternary period, if not, indeed, from its very commencement, he had already acquired his human characteristics. This generalisation at once throws us back to the tertiary period in our search for man's early appearance in Europe. Another fact—disclosed by an analysis of his present corporeal structure—is that, during a certain phase of his previous existence, he passed through a stage when his limbs, like those of the present anthropoid apes, were adapted for an arboreal life. We have therefore to look for the causes which brought about the separation of man from his quadrumanous congeners, and entailed on him such a transformation in his form and habits, in the physical conditions that would supervene on a change from a warm to a cold climate. In the gradual lowering of the temperature of the subtropical climate which prevailed in Central Europe and the corresponding parts of Asia during the Miocene and Pliocene periods, and which culminated in the great Ice age, together with the concurrent changes in the distribution of land, seas, and mountains, we have the most probable explanation of these causes. Whether man forsook his arboreal habits and took to the plains from overcrowding of his own species in search of different kinds of food, before this cold period subjected him to its intensely adverse circumstances, it would be idle for me to offer an opinion. Equally conjectural would it be to inquire into the exact circumstances which led him to depend exclusively on his posterior limbs for locomotion.

During this early and transitional period in man's career there was no room for ethics. Might was right, whether it emanated from the strength of the arm, the skill of the hand, or the cunning of the brain. Life and death combats would decide the fate of many competing races. The weak would succumb to the strong, and ultimately there would survive only such as could hold their own by flight, strength, agility, or skill, just as we find among the races of man at the present day.

In summing up these somewhat discursive observations, let me just emphasise the main points of the argument. With the attainment of the erect position, and the consequent specialisation of his limbs into hands and feet, man entered on a new phase of existence. With the advantage of manipulative organs and a progressive brain he became *Homo sapiens*, and gradually developed a capacity to understand and utilise the forces of nature. As a handicraftsman he fashioned tools and weapons, with the skilful use of which he got the mastery over all other animals. With a knowledge of the uses of fire, the art of cooking his food, and the power of fabricating materials for clothing his body, he accommodated himself to the vicissitudes of climate, and so greatly extended his habitable area on the globe. As ages rolled on he accumulated more and more of the secrets of nature, and every such addition widened the basis for further discoveries. Thus commenced the grandest revolution the organic world has ever undergone—a revolution which culminated in the transformation of a brute into civilised man. During this long transitional period mankind encountered many difficulties, perhaps the most formidable being due to the internecine struggles of inimical members of their own species. In these circumstances the cosmic processes, formerly all-powerful so long as they acted only through the constitution of the individual, were of less potency than the acquired ingenuity and aptitude of man himself. Hence local combinations for the protection of common interests became necessary, and with the rise of social organisations the safety of the individual became merged in that of the community. The recognition of the principle of the division of labour laid the foundations of subsequent nationalities, arts, and sciences. Coincident with the rise of such institutions sprung up the germs of order, law, and ethics. The progress of humanity on these novel lines was slow, but in the main steadily upwards. No doubt the advanced centres of the various civilisations would oscillate, as they still do, from one region to another, according as some new discovery gave a preponderance of skill to one race over its opponents. Thus the civilised world of modern times came to be fashioned, the outcome of which has been the creation of a special code of social and moral laws for the protection and guidance of humanity. Obedience to its behests is virtue, and this, to use the recent words of a profound thinker, "involves a course of conduct which in all respects is opposed to that which leads to success in the cosmic struggle for existence. In place of ruthless self-assertion it demands self-restraint; in place of thrusting aside or treading down all competitors, it requires that the individual shall not merely respect but shall help his fellows; its influence is directed, not so much to the survival of the fittest, as to the fitting of as many as possible to survive. It repudiates the gladiatorial theory of existence. It demands that each man who enters into the enjoyment of the advantages of a polity shall be mindful of his debt to those who have laboriously constructed it, and shall take heed that no act of his weakens the fabric in which he has been permitted to live. Laws and moral precepts are directed to the end of curbing the cosmic process and reminding the individual of his duty to the community, to the protection and influence of which he owes, if not existence itself, at least the life of something better than a brutal savage." (Huxley, on "Evolution and Ethics," p. 33.)

These humble remarks will convey to your mind some idea of the scientific interest and profound human sympathies evoked by the far-reaching problems which fall to be discussed in this section. Contrasting the present state of anthropological science with its position some thirty or forty years ago, we can only marvel at the thoroughness of the change that has taken place in favour of its doctrines. Now man's immense antiquity is accepted by a vast majority of the most thoughtful men, and his place in nature, as a derivative animal at the head of the great chain of life, appeals for elucidation to all sciences and to all legitimate methods of research. But among the joyful pæans of this triumphal march, we still hear some discordant notes—notes, however, which seem to me to die with their echoes, and to have as little effect on scientific progress as the whistling of an idle wind. For my own part I cannot believe that a science which seeks in the spirit of truth to trace the mysteries of human life and civilisation to their primary rootlets, a science which aims at purging our beliefs of superstitious figments generated in days when scientific methods were too feeble to expose the errors on which they were founded, a science which reminds us in a thousand ways that success in life depends on a correct knowledge of the cosmic forces around us, can be opposed to the highest and most durable interests of humanity.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Thieving of Assyrian Antiquities.

I HAD hoped that the British Museum slander case, which was decided a few weeks ago at the High Court of Justice, in regard to the calumnies which were circulated against me, would have silenced then and for ever my would-be detractors; but the review of the trial which appeared in the impression of NATURE of the 10th ult. indicates that misrepresentations are still rife, though an English Court of Justice has already sifted the matter, and gave its verdict in my favour.

2. I must answer your allegations one by one; and I ask you on public grounds to be so good as to insert my reply in the next issue of NATURE.

3. In the first place, you say "We have not referred to the case earlier, as we had hoped that some action in the public interest would have been taken by the trustees of the British Museum, which would have carried the matter a stage further. For this action however we have waited in vain."

4 The above remark plainly shows that you are not aware that I have been appealing for some time past to the trustees for a Court of Inquiry into the alleged robbery of public property, but the British Museum executive authorities persisted in refusing it. If you refer to the fourth day's trial, reported meagrely in the daily journals, you will see that I was the one who felt aggrieved that the alleged robbery of antiquities was not inquired into. The Judge was most explicit on this point, and remarked that in consequence of my representations having been ignored by the British Museum authorities I was justified in bringing my case before a Law Court.

5. Then you say, "From the evidence elicited at the trial it appeared that soon after Mr. Rassam began to dig in Babylonia, collections of tablets found their way into the London market, and these were bought by the British Museum for considerable sums of money." (*Times*, July 1.)

6. Here you are adverting to a vague evidence which was not established in Court; and if I had been called upon to controvert it, I could have shown then and there the fallacy of it, seeing that the British Museum acquired by purchase, through the late Mr. George Smith, Babylonian antiquities five years before I commenced work in Southern Mesopotamia. As a matter of fact, such antiquities have been obtainable from Armenian and Jewish dealers long before the trustees of the British Museum ever thought of conducting researches in those parts. Even I, myself, purchased a collection of tablets at Baghdad for the British Museum in 1877, long before I commenced work there, and that was by instruction from the Museum authorities.

7. Further on you state, "Now as no other excavations were being carried on except by the British Government, and as the internal evidence of the tablets indicated that those which they received from Mr. Rassam as the result of his works and those which they purchased had the same origin, it was natural that the public department should begin to grow uneasy. And this feeling became stronger when it was found that the tablets purchased were of much greater value archæologically and historically than those which arrived at the British Museum from Mr. Rassam."

8. The whole of the above assertions are contrary to known facts and the evidence which was adduced before the Court. Excavations by the Arabs have been carried on in Babylonia from time immemorial, and as the land belongs to subjects of the Sultan, and not to the British Government, I do not know by what right you think that the British Museum can prevent others from digging and from selling what they can find to whomsoever they choose.

9. As for the "public department" becoming uneasy, it is difficult to understand when and how such an uneasiness began and what caused it. I was always on intimate and friendly terms, as our correspondence shows, with the late Dr. Birch, the head of the Department of Assyrian and Babylonian Antiquities, until he died in 1885, or three years after my explorations ceased; and I was also in constant communication with the then Principal Librarian, Mr. Bond, until he resigned in 1888, or six years after the stoppage of the British Museum works in Babylonia; and neither he nor Dr. Birch ever made any complaint to me touching the alleged robbery of public property, though I was the only person who could have taken cognisance of the matter.

10. Then you go on to assert that the feeling of uneasiness became stronger when it was found that the tablets purchased were of much greater value, archæologically and historically, than those sent by me. I am certainly surprised at this remark, seeing that no public inquiry ever took place regarding the value of my discoveries.

11. Then you go on to say, "Speaking broadly, it seems from the evidence that Mr. Rassam sent home 134,000 pieces of inscribed clay from Babylonia, and of these more than 125,000 are what Sir Henry Rawlinson, Mr. Maunde Thompson, and Dr. Wallis Budge style 'rubbish.' (*Standard*, June 30, *Times*, July 3.) This represented the direct return for the outlay. What did go wrong we cannot say, but the outsider will certainly think that something did go wrong in this matter."

12. Here again you are asserting what is contrary to facts, as it is known all over Europe that I am the discoverer of Sippara or Sephervaim, and many temples and palaces in Assyria and Babylonia, from where I sent to the British Museum many valuable collections; and the 134,000 fragments were part and parcel of them. You seem to have overlooked the evidence of one of the best Assyrian scholars who is the senior assistant in the department of Babylonian and Assyrian antiquities at the British Museum, as to the value of the fragments.

13. In regard to Sir Henry Rawlinson's saying that the fragments belonging to a certain collection being "rubbish," it is certainly most startling. As you do not say where this information was obtained from, I take it for granted that it was supplied from the British Museum. Sir Henry Rawlinson would have been the very first man to condemn me if I had allowed any of the fragments to be thrown away, seeing that a mere particle might fit a broken tablet and complete an important text.

14. Further on you state that "The information which he gathered on all these points he sent home to the British Museum in the form of reports, one of the results of which was the dismissal of the native agent. On two subsequent occasions Dr. Budge visited Assyria and Babylonia, and carried on excavations for the trustees, and he acquired some thousands of tablets."

15. It is very extraordinary that the official report you quote above was withheld by the British Museum authorities from being produced in Court as a privileged document, because it contained matters which would be prejudicial to the public service, and yet a part of its contents is now revealed in NATURE.

16. In continuation of the above remarks you go on to say, "It will easily be guessed that from first to last a very considerable sum of public money, amounting to tens of thousands of pounds, has thus been spent upon excavations in Assyria and Babylonia, and the question naturally arises, Has this money been spent judiciously, and has the nation obtained what it had a right to expect in return for its money?"

17. I have no hesitation, in answer to the above remark, to say that my greatest desire is that the public *should insist* upon an open Court of Inquiry into the manner the British Museum executive authorities have carried on lately their Assyrian and Babylonian archæological researches, and find out whether the enormous amount was spent "judiciously" by the different agents they have employed.

18. You further say, "Sales at auctions have revealed the fact that sundry gentlemen had been able to acquire Assyrian slabs from the palaces of Assyrian kings, and as the excavations were carried on by the Government it is difficult to account for this fact. The public has a right to know how property of this nature came into private hands, and the question must be asked until it is satisfactorily answered. The matter cannot be allowed to rest where it is."

19. I do not know what you mean by "Assyrian slabs" having been acquired by purchase, as I know of no such sale

having taken place in England or elsewhere. I am the only explorer, after M. Botta and Sir Henry Layard, who discovered "Assyrian slabs," or bas-reliefs, but that was thirty-eight years ago; and as there have been no sculptured slabs discovered in Babylonia, it is difficult to know what is to be understood by such an assertion. I do certainly agree with you that the matter ought not to be allowed to rest, but that the public should insist upon a thorough examination into the matter.

20. In conclusion, I must touch upon one more point, which appeared near the end of the criticism under discussion, about the duty of public servants to their superiors. You say, "With the terror of the decision in this case before them, all members of the public service will be in duty bound to consider whether they are able to afford the expenses of an action at law, and the enormous costs which follow in its train, before they report unpleasant truths to their superiors."

21. It will be indeed a sad day for an old public servant, who has spent the best part of his life in the service of his adopted country, and held with undiminished confidence important appointments of trust under the Crown, to be debarred from obtaining justice elsewhere when it is denied him by the department under which he served with honour, credit, and success for many a year, when his character is unjustifiably assailed.

6 Gloucester Walk, Kensington, W. H. RASSAM.

[WE are much surprised that Mr. Rassam has taken our article as personal to himself, as we dealt with the thefts in question only from a public point of view, and they might have happened, we suppose, if Mr. Rassam had never existed.

We make the following comments on some of his paragraphs:—

Para. 4. We were not aware that Mr. Rassam had been appealing for a Court of Inquiry. There is no doubt that cause has been shown for a Treasury inquiry in the interests of the public and future explorers, and we hope it will be pressed for.

Para. 6. It was no part of our duty to *sift* the evidence. The point is that evidence was *given* (see *Pall Mall Gazette*, June 30). Did not the British Museum accountant go into the witness-box to state the amounts paid for tablets? and was not the evidence dispensed with because Dr. Budge's "vague" evidence was accepted as sufficient?

Paras. 7 *and* 8. We referred to the evidence given in Court. What else could we do? It was not disproved in Court, or we should have said so.

Para. 9. This is a statement with which only the Trustees of the British Museum can deal. We, of course, are bound to accept Mr. Rassam's statement as he makes it.

Para. 10. We do not quite seize the point of Mr. Rassam's remark here. The statement as to the greater value of the tablets *not* received from him was made by the defendant; it is not ours.

Paras. 11 *and* 12. We can only repeat that the public is interested in knowing that of 134,000 pieces of inscribed clay sent home from Babylonia—it really does not matter by whom, 125,000 have been termed rubbish by Sir H. Rawlinson one of the trustees, the principal librarian, and the present keeper of the collection. It was not necessary to refer to any subordinate official, or to point out the singular fact that he gave evidence contrary to that of three of his official superiors.

Para. 13. We quite agree that it is most startling to hear that, in Sir Henry Rawlinson's opinion, so much of what Mr. Rassam sent home was rubbish. We presume that Mr. Rassam was startled when Sir Henry Rawlinson's deposition was read in Court; that is the reason, perhaps, that he forgot it, as he appears to have done.

Para. 15. Dr. Budge's reports could not be revealed by us because we do not possess them, and have never seen them. All the facts stated were given in evidence to which alone we professed to refer.

Para. 17. Here we cordially agree with Mr. Rassam; as before stated, in our opinion a Treasury inquiry into the expenditure of the public funds on, and the method of carrying out, excavations in the region in question since, say, 1846, is most desirable.

Paras. 18 *and* 19. The article was not written by an expert, and perhaps the word "bas-relief" would have been better than "slab." But there is no doubt about what we mean. Murray's "Handbook to Dorsetshire" informs us that at Canford Hall "a gallery connected with the house by a cloister is devoted to a series of Assyrian sculptures brought from Nineveh." These sculptures—not to call them slabs—are described as "winged lions and bulls, bas-reliefs, &c., similar to those in the British Museum." Now, if there are many such galleries in England, and the objects were obtained at a low price, the whole question of excavation at the public expense is raised.—ED. NATURE.]

Bishop's Ring.

BISHOP'S RING still continues very conspicuous about sunset more so than it was for a long time previous to last November, though not so much so as at the end of 1883. It is evident there must have been an addition of some kind to the dust of our atmosphere last November, a considerable part of which yet remains. The light-coloured dust wisps reappeared faintly after the date (April 10) of my letter (p. 582), but have now entirely disappeared again (I have not seen them since July 20); the texture of the sky in the ring being perfectly smooth lately. I have not seen any other peculiar sunset phenomena of late, though Señor Arcimis (Director of the Meteorological Institute) tells me the sunsets are very brilliant at Madrid. He says he is satisfied that Bishop's Ring did not exist in Spain before the Krakatoa eruption; and he agrees with me that it has never since entirely disappeared about sunset.

Sunderland, September 11. T. W. BACKHOUSE.

Spring and Autumn of 1893.

As the peculiarities of this season are receiving attention in your pages, the following notes of things in this part of England may perhaps interest some of your readers.

On March 25 the following flowers were in bloom:—

Adoxa.	Hazel (nearly over).
Golden Saxifrage.	Larch.
Speedwell.	Celandine.
Wood Sorrel.	Cuckoo flower.
Snowdrop.	Star-wort.
Crocus (nearly over).	Broom.
Grape-hyacinth.	Peach.
Wood anemone.	Gooseberry.
Primrose.	Currant.
Violet (the white, nearly over).	Willow (nearly over).
	Cherry.

At the same date, the elm had been in flower for weeks; the ash was in full bud; one or two sycamores in leaf; chestnuts in early leaf, and showing flower buds. The helibore had been out long ago; hyacinths were beginning to flower; a few pear buds had burst; the elms and hawthorns had shown green for several days. Butterflies had been seen for several days.

The early heat did not, I suspect, suit all our spring flowers. I saw scarcely anything this year of two of our wall-plants which are usually abundant—the *Draba verna* and the *Saxifraga tridactylites*.

On March 27 bluebells were found in flower.

The state of things now on September 12 is as curious.

The wild roses (both *Rosa canina* and *arvensis*) are again flowering in the hedges—in some cases in great profusion; there are now, or a few days ago have been, in blossom the following:

Apple.	Glastonbury thorn.
Pear.	Kerria.
Holly.	Wild strawberry.
Buberis Darwini.	Dog violets.
Rhododendron.	

Some of the autumn flowers appear to me to have suffered from the heat and, perhaps, the drought. I have not seen the *Spiranthes autumnalis*, usually quite abundant here; and the *Colchicum autumnale* has been far less abundant than usual. Some garden bulbs have probably suffered in the same way.

I may add that wasps have been in extraordinary numbers; and that we have found two or three of the nests of the tree-wasp similar to the one depicted in your paper on the 7th inst.

Failand, near Bristol, September 12. EDW. FRY.

NOTES.

MR. W. SAVILLE-KENT, at present engaged as Commissioner of Fisheries to the Government of Western Australia, has shipped to London a large collection of the stony corals, *Madreporaria*, peculiar to the Western Australian coast line. These specimens, added to the extensive series indigenous to the northern and eastern districts of Australia recently contributed by him to the National Natural History Museum, and which were amassed in association with the explorations that formed the basis of his recently published work on the Australian Great Barrier Reef, will constitute the most complete collection of Australasian *Madreporaria* that has yet been brought together. This latest Western Australian consignment includes several specimens of abnormally large dimensions that should make an interesting display in the Natural History galleries. Mr. Saville-Kent anticipates completing his Australian engagements, and returning permanently to England about twelve months from the present date.

The French *Journal Officiel* has just published a decree for the organisation of the proposed Paris Universal Exhibition of 1900. M. Alfred Picard, who, it will be remembered, filled the office of *Rapporteur Général* for the 1889 Exhibition, has been appointed Commissary-General. He will be assisted by a consultative committee of 100 members.

The next meeting of the Japan Society will be held at 20 Hanover-square, on Wednesday, September 27, when Prof. John Milne will read "A Short Account of Volcanic and Earthquake Phenomena of Japan." The paper will be illustrated by photographic lantern slides, and will be followed by an exhibition of photographic slides illustrating life, customs, and scenery of Japan. The meeting would under ordinary circumstances have taken place in October; it has, however, to be held in September in consequence of Prof. Milne having to return to Japan on September 29.

The Congress of the Photographic Society of Great Britain and affiliated societies for the present year will take place on October 10, 11, and 12. The opening meeting, at which the President's annual address will be delivered, is to be held at the gallery of the Royal Society of Painters in Water Colours. The other meetings will be held in the theatre of the Society of Arts.

We hear that Mr. Max Muspratt has just gained the diploma of Chemistry awarded annually by the Swiss Government to a limited number of students for exceptional proficiency in the scientific and technical knowledge of chemistry. Mr. Muspratt, who went to Zurich direct from Clifton College, is the first Englishman to gain this distinction.

We learn from the *Lancet* that an interesting experiment is to be made in connection with next year's meeting of the Norwegian Medical Congress. At the meeting recently held in Christiania it was decided that next year members shall assemble on board a yacht, which will cruise during their deliberations. Weather and other things being favourable, the experiment should prove a very admirable mode of combining business with pleasure.

The *Ceylon Observer* for August 18 has a moderately worded editorial urging the establishment of a zoological garden in Colombo, especially for the purpose of giving the many visitors who pass through Colombo an opportunity of seeing for themselves how rich and varied is the fauna of Ceylon. The *Observer* is confident that the fees paid for viewing the collection would suffice to pay the whole, or nearly the whole, of the expenses which would be incurred.

According to the *Pharmaceutical Journal*, the Kew Herbarium has recently been enriched by the addition of forty-six dried specimens of ferns collected in Sarawak, including six new species; two hundred species of plants collected by Sintenis in Kastamuni (the ancient Paphlagonia), Asia Minor; twelve hundred dried plants collected in Kashmir; one hundred and thirty-nine specimens of Mexican plants; and one hundred and twenty-nine of the Greenland and Iceland flora.

An artificial horizon invented and recently patented by Mr. W. P. Shadbolt, possesses several advantages over other forms. The surface of the mercury is never exposed to the air, hence it does not easily become contaminated, and is also protected from wind. Further, loss of mercury is entirely prevented, thus dispensing with the necessity for taking any extra supply. The instrument permits very small altitudes to be observed, and after having it under trial for more than a year in tropical Africa, under circumstances entailing a good deal of rough usage, Mr. Shadbolt reports that its behaviour was most satisfactory.

The general report of the operations of the survey of India during the survey year ending September 30, 1892, has been issued. From it we learn that the area surveyed in detail during the year amounts to 80,101 square miles. In addition to this, transverse operations have been carried on over an area of 5921 miles. By the measurement of six arcs of longitude the original scheme of differential longitude determination within India proper has been completed. Colonel Waterhouse reports upon a method he has been using to prepare a very sensitive orthochromatic collodion-bromide emulsion. Plates coated with this new emulsion require to be used in a moist state in order to obtain maximum sensitiveness and clear negatives. But wet-plates are inconvenient, and if some means could be found of preparing equally sensitive dry-plates, the process would possess consderable advantages.

We learn from the *Botanical Gazette* that forty professed botanists are now engaged in botanical research at the fifty-four Agricultural Experiment Stations in the United States. Of this number ten are also working in entomology, three in horticulture, one in arboriculture, and one in meteorology.

No. 2 of the *Illustrated Archæologist* has just reached us. It is, if possible, more tastefully got up than No. 1, and archæologists will indeed be hard to please if they cannot find something to interest them among the eight items which go to make up the present number. Among the articles we notice "Stonehenge," by Edgar Barclay; "Notes on some of the Sculptured Tombstones of Argyllshire," by R. C. Graham; and "The Roman City of Silchester," by H. W. Young; while Prof. A. C. Haddon writes on "Wood-Carving in the Trobriands." The magazine is published by Mr. C. J. Clark, 4 Lincoln's-inn-fields.

Prof. John Milne, F.R.S., has brought out, through Messrs. Crosby Lockwood and Son, a little work of which he is the compiler, and which should be very serviceable to the class for which it is intended, viz. students and others interested in mining matters. The title of the book is "The Miner's Handbook," and is a reprint, with corrections and additions, of a compilation, the first part of which was printed at Tokio some fourteen years ago. The little volume is of handy size, has rounded corners, making it suitable for carrying in the pocket, and, with the exception of the title-page, preface, and contents, was printed (and printed well) in Japan.

We have received from the Australian Museum, Sydney, Part III. (Gasteropoda) of the "Catalogue of the Marine Shells of Australia and Tasmania," by J. Brazier. The author, in a prefatory note, says, "The present part contains only the genus Murex. The remaining genera are not included, from causes beyond my control."

Mr. D. Forbes, 29, Victoria-street, Bristol, has sent us the catalogue of a very interesting exhibit at the Bristol Industrial and Fine Art Exhibition. It is that of the collection formed by Mr. F. Mockler, of portraits, diplomas, freedoms, grants, presentations, addresses, visiting-books, correspondence, pamphlets, printed works, manuscripts, &c., once the property of the discoverer of Vaccination. The catalogue is prefaced by a brief memoir of Dr. Jenner.

THE September number of the *Board of Trade Journal* contains an interesting account of the development of the World's Telephones, by M. Daniel Bellet, translated from the *Economiste Francais*, "A Summary of Agricultural Returns of Great Britain for 1893," "Coal Production in Japan," and many other items of interest.

WE have just received the Proceedings and Transactions of the Royal Society of Canada for the year 1892. The London agent for it is Mr. Bernard Quaritch.

A LIST of observations made in 1892 by the members of the Caradoc Field Club, Shropshire, and others, has been issued under the title, "The Caradoc Record of Bare Facts."

THE report for 1892 of the Botanical Exchange Club of the British Isles has just reached us. It is issued by Messrs. James Collins and Co., Manchester.

THE Calendar of the Durham College of Science, Newcastle-on-Tyne, for the session 1893–94 has reached us. It is published by Messrs. Andrew Reid, Sons, and Co., London, and Newcastle-on-Tyne.

MESSRS. F. AND E. GIBBONS, Liverpool, have issued prospectuses of Day Classes in Arts and Science, and of the Evening Lectures, and of the Department of Engineering, in connection with the University College, Liverpool, for the session 1893–94. They contain all the preliminary information which intending students are likely to require.

THE Calendar for 1893–94 of the Glasgow and West of Scotland Technical College has just been published by Mr. Robert Anderson, Glasgow.

DR. W. H. PEARSE has sent us a copy of the address delivered by him as president of the Plymouth Institution and Devon and Cornwall Natural History Society, at the opening meeting of the session 1892–93. It deals with the subject of our present knowledge of biological science.

WE have received a printed circular signed "A Free Lance," condemning a recent action of ours in refusing to print a letter from the author on the subject of the "Publication of Physical Papers" unless, in accordance with the rule to which attention is drawn in every number of NATURE, he divulged his name. We fail to see any adequate reason for violating our rule in the favour of "A Free Lance" more than in the case of any other of our correspondents.

THE products of the sublimation of arsenic form the subject of an important communication to the latest number of the *Zeitschrift für Anorganische Chemie*, by Dr. Retgers. The various allotropic modifications of the element have been subjected to a searching investigation, and further interesting information has been acquired concerning the little known solid hydride of arsenic AsH, and the suboxide As_2O, whose existence has hitherto been considered doubtful. It is first shown that there is no amorphous modification of arsenic, the deposit of so called "black amorphous arsenic," obtained during the sublimation of the element in a current of hydrogen and in a number of high temperature decompositions of arsenic compounds, is found to be microcrystalline and to exhibit distinct evidence that it consists of the ordinary regular variety. There are consequently only two well-defined allotropic modifications of arsenic: (1) the stable form which crystallises in the hexagonal system, is silver-white in appearance, specifically heavy, and requires a comparatively high temperature for volatilisation; and (2) the specifically lighter and more volatile modification which crystallises in regular octahedrons, and exhibits a black surface. When arsenic is heated to the point of sublimation in a current of indifferent gas, the first variety condenses nearest the heated element, while the second variety, owing to its lowe temperature of volatilisation, is deposited more remote from the portion of the tube which is heated by the flame. These two forms of arsenic correspond completely with the two modifications of phosphorus, the regular black variety with the regular yellow modification of phosphorus, and the silver-white hexagonal form with the hexagonal red phosphorus. Dr. Retgers adduces some evidence also in support of the view that there is a third crystalline modification of arsenic, of which the crystals belong to the monoclinic system. The fact is also recorded that elementary arsenic, of whatever modification, is invariably opaque even when in the finest state of division; former observations of yellow and brown transparent arsenic are shown to have been due to compounds having been mistaken for the element. The brown spots which are deposited along with arsenic when the flame from a Marsh's apparatus is allowed to impinge upon cold porcelain, or which form in the Marsh sublimation tube, do not consist of the element in thin layers, but of the brown solid hydride AsH, which is produced by the partial dissociation of the gaseous trihydride AsH_3. When the last-named substance is heated during its passage along the sublimation tube, the arsenic mirror consists of both modifications of the element, the silver-white hexagonal form nearest the flame, and the black regular variety further removed. The brown deposit of solid hydride AsH is always found furthest removed of all, and thus forms, as it were, the tail of the mirror. Dr. Retgers finds that boiling xylene readily dissolves this solid hydride, thus affording an excellent mode of distinguishing it from elementary arsenic, which is totally insoluble in xylene.

THE solid hydride of arsenic was isolated some years ago by Janowsky, who obtained it as a brown velvet-like substance by decomposing potassium or sodium arsenide with water. Ogier has subsequently shown that it may likewise be obtained by the action of the silent electrical discharge upon the gaseous trihydride. The existence of the suboxide of arsenic has hitherto been so doubtful that the compilers of the new edition of "Watt's Dictionary of Chemistry" feel justified in stating that "no definite proof of the existence of an oxide with less oxygen than As_4O_6 has been given." Dr. Retgers, however, adduces weighty evidence in favour of the supposition. As explained above, when arsenic is sublimed in a current of inert gas (carbon dioxide, for instance), a deposit consisting of the two modifications of the element, white and black, is obtained. The moment, however, that a little oxygen or air is allowed to mix with the carbon dioxide a *brown* annulus commences to form between the white and the black elementary deposits. This brown sublimate is not crystalline, and is transparent, the thin films proving to be quite isotropic in polarised light. In order to produce a broad deposit of this brown substance it is advisable to employ a wide tube, and to stop the experiment as soon as the annulus is formed, as further heating soon decomposes it again. From this and further evidence adduced by Dr. Retgers, there can be no longer any reasonable doubt that a lower oxide of arsenic, probably As_2O, is capable of existence.

THE additions to the Zoological Society's Gardens during the past week include a Campbell's Monkey (*Cercopithecus campbelli*, ♀) from West Africa, presented by Miss Jane Richards; a Pig-tailed Monkey (*Macacus nemestrinus*, ♂) from Java, presented by Miss Llewellyn; an Azara's Capuchin (*Cebus azaræ*, ♀) from Paraguay, presented by Miss Hairby; two Common Marmosets (*Hapale jacchus*) from South-East Brazil, presented by Mr. E. Lake; two Lions (*Felis leo*, ♂ ♀) from East Africa, presented by H.H. the Sultan of Zanzibar; two Egyptian Jerboas (*Dipus ægyptius*) from Egypt, presented by Miss B. Dell; two Egyptian Jerboas (*Dipus ægyptius*) from

Egypt, presented by Mr. M. W. Edgley; one Egyptian Jerboa (*Dipus ægyptius*) from Egypt, presented by Mr. W. R. Clark; a Golden Eagle (*Aquila chrysætus*) from Scotland, presented by Mr. Bryan Cookson; a —— Buzzard (*Buteo* ——) from West Africa, presented by Mr. Rice; three Tench (*Tinca vulgaris*) from British Fresh Waters, presented by Mr. Arthur E. Rumsey; two Collared Fruit Bats (*Cynonycteris collaris*), a Wapiti Deer (*Cervus canadensis*, ♂), a Japanese Deer (*Cervus sika*, ♀) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Double Star Measures.—Nos. 3185–86 of the *Astronomischen Nachrichten* contains the micrometrical measures of double stars made by Mr. Tarrant during the years 1889–92. This series is a continuation of that published in a preceding number (2991) of the same journal. The same instrument has been employed as formerly, but its position has been changed, it now being 510 feet above the sea level. Stars with considerable southern declination can thus be much more accurately measured. The objects are arranged in the following order:—Dorpat Catalogue, Pulkova Catalogue, Burnham, and Miscellaneous.

Pubblicazioni della Specola Vaticana.—In the third volume of this publication there are several contributions of interest and importance to which we can here briefly refer. In the Astronomical Section, M. P. G. Lais gives an account of the measurements of the position of Nova Aurigæ (with a photograph), and also a few words on the comets Swift, Holmes, and Brooks. M. P. F. Denza, in addition to a communication on the total eclipse of the moon that occurred on November 4, 1892, gives a summation of the observations made of the shooting stars of August in that year, and of the shooting stars of November in the same year, and also of solar spots, magnetic disturbances, and auroræ. In the Astro-Photographic Section, M. P. G. Lais and F. Mannucci give an account of the work done for the international chart and catalogue of the heavens; twenty-six photographs for the chart, and 115 for the catalogue were taken, while 154 other photographs, including groups of stars, nebulæ, comets, &c., were obtained. These communications are accompanied by some fine photographs, which include the Præsepe group, Nebula of Orion, and some of the sun. M. P. F. Denza communicates most of the articles in the Magnetic Section, while the Meteorological Section contains many important communications, with several diagrams, among which we must mention that on the classification of clouds, by M. F. Mannucci, which is illustrated by a beautiful series of photographs showing the various forms which they assume.

Comet Finlay and the Præsepe.—The ephemeris of Finlay's comet showed that a passage through the star-group Præsepe would take place about the beginning of October. In *Astronomischen Nachrichten*, No. 3187, Prof. A. Berberich gives a comparison of the ephemeris with the star-places in Yarnall's catalogue the measures of C. Wolf and Winnecke giving the following table of conjunctions. (γ. Pr. = number in Yarnall's catalogue):—

γ. Pr.		Conj in R.A. M. T. Paris. h		Comet-Star $\Delta\delta$ ′

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 11.—M. Lœwy in the chair.—Treatment of vines infested by *Phylloxera* with peat moss impregnated with schist, by M. F. de Mély. The results of the treatment proposed last year have been controlled by the Inspector-General of Agriculture and by the Inspector-General of the Compagnie de Lyon. As a consequence of their visit, the Minister of Agriculture has sent Dr. Crolas, of Lyon, to organise further applications of the method. A vine already attacked by *Phylloxera* has been under treatment since June, and although some of the insects have survived, the vine has not turned yellow. The portion of the vineyard treated by this method for two seasons has retained its rootlets in a perfect state, and those vines which were treated with the maximum dose—viz. 2 kgr. of the mixture, containing 200 grs. of pure schist, show no trace of *Phylloxera*.—Magnetic observations recently made in Russia by M. Venukoff. Observations at about a hundred stations comprised between 45° 11′ and 36° 42′ of latitude, and 65° 47′ and 82°·17′ of longitude east of Greenwich prove that the isogonal lines inserted in Berghaus's *Physikalischer Atlas* are not exact for Central Asia; in particular, the degrees of declination accepted are too large. Local variations of the magnetic elements in European Russia have recently been investigated, and some very large disturbances have been discovered. In the province of Grodno the magnetic declination was found to change by 10° in a distance of 21 km., and in the neighbourhood of Belgorod the deviation mounted up to 180° in a space of a few tens of square km. This implies the presence of a small and perfectly local magnetic pole. It must be remembered that in the Neva delta the fortress of St. Peter and Paul is known to deflect the magnetic needle by 10°.—Presence of a ferment analogous to emulsine in mushrooms, and particularly in parasitic mushrooms of trees or those growing on wood, by M. Em. Bourquelot. It is proved that several mushrooms, and especially those developing on living or dead wood, contain a soluble ferment possessing the property of doubling various glucosides, such as amygdaline, salicine, and coniferine. It is not possible to say that this ferment is identical with the emulsine of the almonds, but it acts in the same manner and upon the same substances. This ferment was found in two ways. In one, the fresh mushroom was placed in a saturated atmosphere of ether or chloroform vapour, which produces an abundant exudation of liquid holding in solution a large portion of the principles contained in the cellular juice. This liquid was placed for 24 or 48 hours in direct contact with a solution of a glucoside; or an aqueous solution was formed by precipitation with alcohol, and treated in the same manner. In the second process, the mushroom was triturated with sand and transformed into a paste; this paste was treated with distilled water and filtered off, the liquid being used as before. One specimen, picked from an elder branch, gave a liquid which completely converted a dose of coniferine into grape-sugar in the course of three days. The ferment is limited to fungi living on wood, enabling them to assimilate the glucosides contained in it.—On a method of determining the density of gases for industrial purposes, by M. Maurice Meslans.

THURSDAY, SEPTEMBER 28, 1893.

THE PHYSIOLOGICAL PAPERS OF PROF. SACHS.

Gesammelte Abhandlungen über Pflanzen-physiologie. Von Julius Sachs. 2 vols., with 126 woodcuts and 10 plates. (Leipzig, 1892-3.)

THIS excellent collected edition of Prof. Sachs's chief contributions to the physiology of plants will e welcome to all botanists. The author in his preface xplains the very sufficient reasons which have led him o publish this collection, and the principles which have uided him in the choice of papers. He has not thought necessary to reproduce all his physiological treatises, ut has more especially aimed at selecting such as deal ith matters of fact rather than theory, while some which e considers to be sufficiently well known already are mitted.

Such a collection is a great help to the reader, and es- ecially so when it is compiled by the author himself. In his case we do not merely obtain a series of isolated apers, but have the further advantage of learning the uthor's mature view of the relative importance of his wn researches.

Many of the papers have been abridged, and some are nly given in abstract. In many cases notes have een added, which are not the least interesting part of e work, as they often indicate the author's latest views n the questions at issue.

To review adequately a collection of Prof. Sachs's hysiological treatises would be to write the history of egetable physiology from 1859 onwards. Such an at- mpt is out of the question; only a very short sketch the contents of this book can be given here.

The selected papers, 43 in number, are arranged, ac- ording to subject, in nine groups; within each group the der observed is chronological. The first volume con- ins works concerned chiefly with the chemical and ysical phenomena of vegetation, while those contained the second volume are on growth, cell-formation, and ritability.

The first section contains essays on the action of heat n plants. The first, published in 1860, is on the effects frost. The observations described will be remembered all readers of Prof. Sachs's text-book. There is much om for further research on the effects of low tempera- res on various plants, and the subject is obviously of actical as well as of physiological interest.

Other papers in this group are on the dependence of rmination on temperature, on transitory rigidity in ir- table organs, on the superior limit of temperature as ecting vegetation, and on the influence of temperature the formation of chlorophyll. All these investigations e of fundamental importance; the same perhaps can arcely be said of the last paper in this part, "On Emul- on Figures and the Grouping of Swarm-spores in ater," which is merely concerned with a possible urce of error in observations on the movements of icellular organisms.

The succeeding section, on the action of light on plants, cludes some of the best known of the author's researches, the most important perhaps being that on the effect of light of different colours on assimilation and growth. It is a little disappointing, however, to find no reference in the notes to the more recent and exact work of Timiriazeff, Engelmann, and others. The latest published paper in this section, "On the Action of the Ultra-violet Rays on the Formation of Flowers" (1883 and 1886), is probably less familiar to physiologists than the others. In this, Prof. Sachs brings forward evidence to show that when, in the case of a green plant, the ultra-violet rays alone are excluded, the development of flowers is hindered, though otherwise the plant grows normally. The conclusion which he arrives at is that the ultra-violet rays produce, in the green leaves, the "flower-forming substances."

The third group of papers, on chlorophyll and assimilation, is certainly among the most important in the collection, for by means of these researches the author first proved that the chlorophyll corpuscle is the organ of assimilation, a fact which forms the basis of the whole physiology of nutrition in plants. The investigations, dating from 1862, by which Prof. Sachs showed that starch appears in the chlorophyll corpuscles as a result (though, as we now know, not an *immediate* result) of assimilation, are of special interest at the present moment, in view of the new light recently thrown on this whole subject by the work of Messrs. Brown and Morris.

Later papers in the same section are those "On the Activity of Nutrition in Leaves" (1884), and on "The Treatment of Chlorotic Plants" (1888). The former is devoted chiefly to the determination of the energy of assimilation in the leaves of various plants. The latter is the only paper in the collection written with a "purely practical" object, namely to teach the most convenient and effective method of applying iron salts as manure to plants which, from want of iron, fail to develope their chlorophyll.

The fourth section includes the work on the movements of water in plants. Among other researches of importance, we here find the well-known treatises "On the Ascending Current of Sap in Transpiring Plants" (1877-8) and "On the Porosity of Wood" (1877-9). The former contains the author's classical determinations of the rate of ascent of the sap, by means of the Lithium spectroscopic method, while in the latter his famous "imbibition theory," according to which the water rises in the substance of the lignified cell-walls, is developed. This theory is no longer accepted by physiologists, but the author justly points out that the facts given in the paper maintain their value quite independently of the truth of his theoretical conclusions.

The papers of the fifth group, on the behaviour of the constructive materials during growth, are all of early date (1859-63), and the author regards their interest as being mainly historical. To us they seem to be among the most attractive in the collection. Most of them relate to the phenomena of germination, and especially to the changes undergone, during that period, by the reserve food substances, while many facts of morphological and histological interest are also told us.

Going on to the second volume, we find in the sixth section of the work the author's researches on the subject of growth, which he carried out with the help of the various forms of auxanometer invented by him. His results, which first established the extreme complexity of the conditions on which the rate of growth in plants depends, are familiar to readers of his text-book and lectures.

The seventh section contains the papers on "tropisms," *i.e.* the reactions of growing organs under the stimuli of gravitation, light, and moisture. The last paper in the group, that on orthotropous and plagiotropous organs, seems to us to be of the widest interest, as offering a contribution towards the solution of the most fundamental and most difficult of all biological problems, namely the question of the *causes* of the forms of organisms. This in the author's phrase is the problem of "scientific morphology."

Section VIII., on the relations between cell-formation and growth, includes the two well-known papers on the arrangement of cells (1878–9) in which the form of the network of cell-walls is explained with the help of the law of their rectangular intersection. The author shows how, in organs of similar outline, identical arrangements of the cells arise, whatever may be the morphological nature of the organ, so that the cellular structure of a hair, an antheridium, and an embryo may be the same. He has thus given a useful warning to morphologists, who have often laid too much stress on mere cell-arrangement in discussing embryological and other similar questions.

The last paper in this section is on "Energids and Cells." As it is the most recent of all (1892), and probably the only one in the book which may not yet be familiar to botanical readers, a short account of its contents may be useful.

Under the term *energid*, Prof. Sachs understands a single nucleus, together with the protoplasm governed by it, the two together forming a whole, which is an organic unit, both in the morphological and physiological sense. He has chosen the name energid in order to express the chief property of the organic unit, namely, that it possesses internal or vital energy. The conception of an energid, as distinct from that of a cell, has become necessary, owing to the discovery in recent years of so many multinucleate cells and multinucleate organisms without cellular structure, discoveries which we chiefly owe to the researches of Schmitz. Such a multinucleate cell or organism, though enclosed within the contour of a single cell-wall, is manifestly equivalent not to a single uninucleate cell, but to a multicellular structure. This is proved by the fact that the portions of protoplasm, each surrounding a nucleus, so often subsequently become free as complete and independent cells, as in the formation of the zoospores of *Saprolegnia*, or form a multicellular tissue, as in the endosperm of many Phanerogams.

It is quite evident that the word *cell* has come to be used in many different and inconsistent senses. As Prof. Sachs says: "According to the prevailing terminology, an empty wood fibre is a cell, so is an embryo-sac containing young endosperm, and so also is an Amœba, or a zoospore, or even an entire Caulerpa." Everyone who has had to teach botany will sympathise with the author in his complaints of the confusion thus caused. While other sciences keep their technical l[anguage] up to date, "the science of living things beg[ins] with a word which arose more than 200 years a[go] in consequence of a mistake." Hence, in his opinio[n] radical change in language is demanded; for the t[rue] histological unit the word *energid* is proposed, while [the] old word *cell* can be retained, either for the cell-w[all] alone (its original sense), or for the cell-wall togetl[her] with its contents, whatever they may be, and wheth[er] including one energid or many.

It appears to us that the change proposed is a real a[nd] great improvement; the only difficulty is our firmly fi[xed] habit of connecting the idea of a histological unit w[ith] the word *cell*. Whether the new term be adopted [or] not, Prof. Sachs has done good service in bring[ing] clearly before us the contradictions between our pres[ent] antiquated phraseology and histological facts as th[ey] are now known to us.

The ninth and last section of the work is on [the] causal relations of the form of plants. It consi[sts] mainly of the two essays on "*Stoff und Form*," wh[ich] have already attracted much attention, and met w[ith] much criticism. The fundamental conception on wh[ich] these essays are based, is the idea that the organs [of] plants owe their form to their substance, just as a crys[tal] owes its form to the chemical constitution of its mo[le]cules. Prof. Sachs, therefore, believes that there m[ust] be a special substance concerned in the formation of ea[ch] kind of organ; there must be a root-forming substan[ce], a shoot-forming substance, a flower-forming su[b]stance, and so on. Of course the quantity [of] the active substance by which form is det[er]mined may be extremely small in comparison with t[he] whole material of which the organ consists. Prof. Sac[hs] supposes that these hypothetical formative substanc[es] are, in the case of green plants, produced in the assim[i]lating organs, and thence conveyed to the seats of develo[p]mental activity. He is inclined to identify the formati[ve] substance with the *nucleine*, and is so far in agreeme[nt] with many modern histologists. He regards the differe[nt] specific formative substances as being possibly varieti[es] of nucleine, comparable to the isomers of grape-sugar, [or] of tartaric acid.

The extremely hypothetical character of the who[le] theory is manifest. There is at present no evidence f[or] the existence of specific formative (*e.g.* "root-forming" or "shoot-forming") substances. Even if we acce[pt] nucleine as representing them, we still have no evidenc[e] that it is formed in the assimilating organs, or indee[d] that it exists, as such, anywhere except in the nucle[us] itself. So far as we know at present it seems that t[he] nucleus forms the nucleine, not the nucleine the nucleu[s]. Until some basis of fact is found for the "*Stoff un[d] Form*" hypothesis, it can only be regarded as a forma[l], not a real explanation of the phenomena, howeve[r] valuable it may be as a stimulus to further enquiry.

An addendum to the last paper gives an extract fro[m] the Lectures on the Physiology of Plants (1st editio[n] 1882), on the continuity of the embryonic substance. [It] certainly seems to us that Prof. Sachs' idea here ex[-]pressed is essentially the same as the conception of th[e] continuity of the germ-plasm, which has played so impor[-]tant a part in recent biology. The form in which th[e] doctrine is put by Prof. Sachs is specially applicable to plants, in which the continuity of the germ-plasm can only be traced through the embryonic substance of the growing points.

This collection, containing what are probably the most important contributions of our time to the physiology of plants, is in itself a marvellous record of scientific activity. As Prof. Sachs is still engaged in physiological research, we may hope that a later edition of the work will contain many further invaluable additions to our knowledge.

D. H. S.

OUR BOOK SHELF.

In English Lagoons. By P. H. Emerson. (London: David Nutt, 1893.)

YET another book about the Norfolk Broads, or, as the author prefers to call them, the "English Lagoons." One can hardly credit that anything fresh could be said on this well-worn subject, but Mr. Emerson's book differs from all that have gone before in being a continuous narrative of a twelve months' sojourn on the Broads in his pleasure wherry, the *Maid of the Mist*, and presents to us a graphic picture of these waters under their winter aspect as well as under a summer sky. Much that he has written, more particularly his excellent descriptions of the peculiar scenery of this remarkable admixture of land and water in mid-winter, is highly interesting. The atmospheric effects under various conditions of storm and sunshine, by moonlight and at early dawn, display a keen artistic perception, but the incidents as a rule are trivial to the extreme in fact, and the constant use of the vernacular becomes tiring—whole chapters (*e.g.* Chapter xxi. of six pages) might have been well omitted.

From a naturalist's point of view the reader cannot fail to be pleased with the kindly spirit which pervades the book, the evident delight which the author took in his feathered friends, and his disgust for the wanton destruction which is too frequently committed by thoughtless visitors to these delightful retreats, but having said this we confess we are rather puzzled by Mr. Emerson's ornithology. On page 216, for instance, he mentions watching a pair of desert wheatears on Palling Sand Hills; surely he cannot have met with *Saxicola deserti* in Norfolk. Scarcely less astonishing is the mention of a blue-headed wagtail's nest, and the appearance of the white wagtail on several occasions. The present writer has known the Broads for forty years, but has never had the good fortune to meet with *Motacilla flava* or *M. alba*, both of which are excessively rare in Norfolk, and probably only occasionally appear as passing spring migrants. Many of the observations on birds are interesting, but the following passage is hardly in good taste. Speaking of Surlingham Broad, "which the late Mr. Stevenson, the local naturalist, loved," Mr. Emerson continues, "But this piece of water is to me dull and shadgless, but then Mr. Stevenson did not know shadows from reflections, nor, I suspect, beauties from commonplaces. As a naturalist, moreover, he was not to be compared to the late Mr. Booth, a true lover of birds and an outdoor life. But in Norfolk every native goose is a swan." Mr. Stevenson's reputation as an ornithologist is too well established to need any defence from my pen, but I can say without hesitation that the best general description of the Broad district ever written is to be found in the introduction to his "Birds of Norfolk," and his chapters descriptive of a summer's night and a summer's day on the very Broad which Mr. Emerson considers so uninteresting, show not only his wonderful powers of observation but his keen perception of the beauty and poetry of nature; even so familiar a bird as the redbreast is invested with fresh interest after reading his charming chapter on this pert little friend of man.

T. S.

The Mechanics of Architecture. By E. Wyndham Tarn, M.A. (Crosby Lockwood and Son, 1892.)

THE modern architect is beginning to perceive that he has allowed the engineer to cover the ground with monstrosities because his immediate predecessors considered that any scientific knowledge would spoil the artistic faculty, regardless of the great architects of the past, Sir Christopher Wren, Leonardo da Vinci, and the designers of our cathedrals.

The theories which the author discusses, as of Pillars, Roofs, Arches, Domes, and Spires, Buttresses and Foundations, are illustrated by numerical applications to well-chosen existing examples; so that the architect will thereby acquire confidence in the formulas, and not lay himself open to disaster in consequence of a mathematical misprint.

Graphical constructions are freely employed, which recommend themselves to the draughtsman, who thinks better on his drawing-board than in symbols and formulas.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Telegony.

THIS is a term which Prof. Weismann has recently coined to designate a class of phenomena which have thus far been pretty generally accepted as of unquestionable occurrence in mammals, if not also in birds. I refer to the alleged influence of a previous sire on the progeny of a subsequent one by the same mother. The most notorious instance of this alleged fact is that of Lord Morton's Arabian chestnut mare, which had her first foal to a quagga. Subsequently she produced two colts by a black Arabian horse. These were both partially dun-coloured, and striped on the legs more plainly than the real hybrid had been. One of the colts was also striped on the neck and some other parts of the body; lastly, the mane in both resembled that of the quagga, being short, stiff, and upright. Darwin, from whom this description is taken, records an almost exactly parallel case, on the authority of Mr. James Weir. He also gives a number of references to other cases, not only in horses, but likewise in sheep, swine, dogs, &c. Within the last twelvemonth another seemingly unmistakable case of the same thing took place in the Zoological Gardens, and is recorded by Mr. Tegetmeier in one of the December numbers of the *Field*. Here the first foal was a hybrid between two species of ass, and the second by a male of the same species as the mother. Not a few further apparently well-authenticated instances might be mentioned, but these are enough for present purposes. Indeed, most breeders and fanciers are so persuaded of the truth of "telegony" as to deem a pedigree animal seriously deteriorated in value if she has been covered by an inferior male, while in Darwin's opinion "there can be no doubt" as to the fact of this influence of a previous sire being occasionally exhibited in mammals, although he expresses himself as doubtful with regard to it in the case of birds.

Prof. Weismann, however, has recently challenged the facts. He has also given his explanation of them, supposing them to be facts. Therefore I will consider these two points separately.

Several years ago I undertook an experimental inquiry upon the subject with dogs, which yielded negative results. I then obtained an introduction to Mr. Everet Millais, in order to profit by his large experience and scientific interest in all matters pertaining to dog-breeding. He suggested that the question ought to be put in the journals of fanciers in this country, and also in America, for the purpose of raising discussions upon it. This was done, with the result of letting loose floods of letters to the journals, and not a few private ones to ourselves. Of course this copious response was for the most part valueless, further than to show a general belief among fanciers and breeders in the facts of telegony, coupled, however, with great differences of opinion touching the frequency of its occurrence. Nevertheless, out of all this medley of unscientific assertion, there were a comparatively few cases where it did not appear that coincidence, pre-formed ideas, mal-observation, atavism, &c., could be reasonably assigned, and these served to indicate the most promising varieties with which to work in future experiments.

The general result of our inquiry thus far has been to corroborate the opinion with which we both started, viz. that although the fact of telegony is of very much rarer occurrence than is generally supposed, it nevertheless does appear to take place occasionally, and especially, as Mr. Herbert Spencer has recently observed, where the first offspring has been a hybrid, as distinguished from a mongrel.

On the other hand, there does not seem to be any good evidence of the phenomenon in the case of mankind. For although I have met with an alleged instance of a white woman who, after having borne children to a negro husband, had a second family to a white one, in which some negro characteristics appeared, I have not been able to meet with any corroboration of this instance. I have made inquiries among medical men in the Southern States of America, where in the days of slavery it was frequently the custom that young negresses should bear their first children to their masters, and their subsequent children to negro husbands; but it never seems to have been observed, according to my correspondents, that these subsequent children were other than pure negroes. Such, however, was not the same case as the one above mentioned, but a reciprocal case; and this may have made a difference.

So much, then, for the facts. As regards their interpretation, Mr. Herbert Spencer says, speaking on behalf of the Lamarckians, "And now, in the presence of these facts, what are we to say? Simply that they are fatal to Weismann's hypothesis. They show that there is none of the alleged independence of the reproductive cells; but that the two sets of cells are in close communion. They prove that while the reproductive cells multiply and arrange themselves during the evolution of the embryo, some of their germ-plasm passes into the mass of somatic-cells constituting the parental body, and becomes a permanent component of it. Further, they necessitate the inference that this introduced germ-plasm, everywhere diffused, is some of it included in the reproductive cells, subsequently formed. And if we thus get a demonstration that the somewhat different units of a foreign germ-plasm permeating the organism, permeate also the subsequently-formed reproductive cells, and affect the structures of the individuals arising from them, the implication is that the like happens with those native units which have been made somewhat different by modified functions: there must be a tendency to inheritance of acquired characters." (*Contemporary Review*, March.)

On the other hand, Prof. Weismann says that, even admitting the facts, they in no way militate against his theory of germ-plasm. For, as he says, "such cases could be accounted for from our point of view by supposing that spermatozoa had reached the ovary after the first sexual union had occurred, and had penetrated into certain ova, which were still immature. The immediate fertilisation of the latter is rendered inconceivable by the fact of this immaturity; but the sperm-cell must have remained in the body of the ovum until the maturation of the latter, with the nucleus of which it then united in the process of amphimixis." ("The Germ-Plasm," pp. 385–6.)

It seems to me that we have here, in principle, a sufficient answer to the Lamarckian interpretation of the facts alleged. I say "in principle," because the obvious objection that mammalian spermatozoa cannot be held capable of delving their way through the stroma of an ovary in order to reach unripe ova, may be obviated by supposing that it is the "ids" and "determinants" of disintegrated spermatozoa which do so. For, if there are any such things as ids and determinants, it is certain (from the facts of atavism) that they can survive the disintegration of their containing spermatozoon, and also that they can then penetrate somatic tissues to any extent.

But I have discussed the whole subject in a lengthy appendix to my recently published "Examination of Weismannism," to which I must refer for all details, both as regards the alleged facts and their rival interpretations. My object in raising the issues in these columns is to ascertain whether further light can be thrown upon the subject by any of your numerous read Therefore I will merely add that numerous experime which during the last eighteen months I have been conduct with birds, have yielded uniformly negative results. Sco of purely bred ducks (white Aylesbury), and dozens purely bred chickens (Polish) have been hatched; but in no case has there been the smallest resemblance to their telegon sires. In some cases a year, and in others only a fortnight allowed to elapse between the successive impregnations; bu all cases the broods are as purely bred as if their respect mothers had not previously borne offspring to males of wid different breeds.

GEORGE J. ROMANES

Christ Church, Oxford, September 16.

Quaternions and Vectors.

IN his recent letter (NATURE, August 17, p. 364), which avowedly a reply to my paper (Proc. R.S.E., 1892–93) "Recent Innovations in Vector Analysis," Prof. Gibbs d not seem to me to discuss the real point at issue.

At the end of that paper I summarised the arguments favour of quaternion vector analysis under five heads.

The first of these was: "The quaternion is as fundamenta geometrical conception as any that Prof. Gibbs has name This argument, which was a direct criticism of Prof. Gibb attack on quaternions in his letter to NATURE of two years a is not even referred to in his recent letter. It may reasonab be assumed that silence means consent.

The second summarised argument was: "In every vec analysis so far developed, the versorial character of vect cannot be got rid of." Regarding this, which was a dir criticism of the position of Mr. Heaviside and Prof. Macfarla I am glad to find that Prof. Gibbs is virtually at one with me, a brings to my support the great names of Lagrange and Poiss Now Hamilton's quaternions is admittedly the only vec calculus which takes direct cognisance and makes full consiste use of this principle, the logical consequences of which form t subject of my third and fourth summarised arguments. Th the quaternion wins all along the line.

The fifth and last summarised argument was: "T invention of new names and new notations has add nothing of importance to what we have already learned fro quaternions." This, probably, has most direct connection wi Prof. Gibbs's recent letter, which is to a large extent an expo tion of his own system. And interesting though this may be itself, it does not really make out a case against quaternion and that, be it remembered, is the point at issue. Indee Prof. Gibbs himself admits that the quaternion notation has certain advantage in simplicity. This is plainly so in the ca of ∇, of which in its quaternionic form Prof. Gibbs gives a ve neat application in an equation whose physical interpretation the solution of an important problem. But in this very conne tion, carried away by the exuberance of his humour, he seem to imagine that the *name* Nabla is of the essence of quaternion and that the quaternionist has no right to use the word potentia

I am not aware that I anywhere expressed a dislike the notations $[\phi]$, ϕ_s, $\phi_\times$, which represent quantities mo emphatically quaternionic, or at least Hamiltonian, in the origin. What I wished to emphasise was that, in gettin at the conception of the quantities ϕ_s, $\phi_\times$, Prof. Gib makes use of the so-called indeterminate product, which is n vector but is analytically the same kind of thing as the quate nion product, and that consequently his pamphlet and his fir letter to NATURE are hardly consistent with each other.

I am accused of an inadvertence in the interpretation certain integrals. I have not Prof. Gibbs's pamphlet by me present, but, if I recollect aright, there is no explicit mentio in it of the restriction that the operand is to be a constant vecto Nor do I see that such a restriction is necessarily implied in system in which operators, whether under an integral sign not, are represented symbolically apart from the operand. Th operand is virtually there all the time. The equations ar meaningless without it. To introduce the unexpressed operan is therefore a very different thing from the act of introducing a altogether extraneous vector. With the required restriction however, it appears that Professor Gibbs's integral operators ar not of such general applicability as had been hoped.

But even granting that I have been guilty of an inadvertenc on this point, that in no way affects the general argumen

Satisfactory reasons have still to be given for deserting the quaternion highway. The asserted weakness of Hamilton's calculus, as contrasted with the implied strength of its rivals, has still to be disclosed.

With a view to bring us all to one mind, Prof. Alfred Lodge suggests (NATURE, June 29) that the quaternion be regarded as the difference of its vector and scalar parts, so that the square of a vector becomes *minus* the scalar product of a vector into itself. It is not easy to see what ultimate advantage this change of sign would bring. The most obvious disadvantage would be that it would to a large extent render Hamilton's and Tait's classical treatises of little service to the student. Moreover, it would bring in the quaternion in a very artificial manner, as a kind of after-thought, so to speak; it would, I think, confuse the beginner by forbidding him to make use of powers of vectors in the way generally familiar in analysis; it would accentuate the importance of the product at the expense of the quotient of vectors; and it would tend to obscure the significance of the versor. I am afraid it is too much to ask of any who have got accustomed to the quaternion method to introduce confusion by such a change of sign. Up to a certain point, and along certain lines, Gibbs's and Heaviside's systems lead to results identical with those obtained by quaternions. It has not been shown that they lead to these results more simply or more directly, or that they are more easily mastered by the student than is the calculus of Hamilton. And the same may be predicted of the modified quaternionic system suggested by Prof. Lodge.

Musselburgh, September 4. C. G. KNOTT.

Grassmann's "Ausdehnungslehre."

SIR ROBERT BALL asks why no one has translated the "Ausdehnungslehre" into English. The answer is as regretable as simple—it would not pay. The number of mathematicians who, after the severe courses of the universities, desire to extend their reading is very small. It is something that a respectable few seek to apply what they have already learnt. The first duty of those who direct the studies of the universities is to provide that students may leave in possession of all the best means of future investigation. That fifty years after publication the principles of the "Ausdehnungslehre" should find no place in English mathematical education is indeed astonishing. Half the time given to such a wearisome subject as Lunar Theory would place a student in possession of many of the delightful surprises of Grassmann's work, and set him thinking for himself. The "Ausdehnungslehre" has won the admiration of too many distinguished mathematicians to remain longer ignored. Clifford said of it: "I may, perhaps, be permitted to express my profound admiration of that extraordinary work, and my conviction that its principles will exercise a vast influence upon the future of mathematical science." Useful or not, the work is "a thing of beauty," and no mathematician of taste should pass it by. It is possible, nay, even likely, that its principles may be taught more simply; but the work should be preserved as a classic.

I should be glad to subscribe £10 towards the expenses of translation. If others will join, perhaps some publisher will take the matter up. Is there no machinery by which the universities could be induced to subscribe?

A good book on the subject, entitled "The Directional Calculus," by Prof. E. W. Hyde, is published by Ginn and Co., Boston; and a valuable and very clever elementary exposition, on a geometrical basis, of important parts of the Calculus, by M. Carvallo, appeared in the *Nouvelles Annales de Mathématiques* of January, 1892. The latter will, in one day, enable a student to comprehend the power and elegance of Grassmann's methods.

R. W. GENESE.

Astronomical Photography.

THE nature of chromatic correction adopted for visual telescopes is uniform enough to make it possible to state what kind of photographic plate is desired for use with such telescopes.

A plate which is sensitive to light between C and F in the solar spectrum, with a marked maximum between D and *b*, and insensitive to other light, would be suitable for nearly all visual telescopes, which might in other respects (*e.g.* aperture, focal length, position as affected by climate) be available for taking special photographic records. With existing plates, so far as I have been able to acquaint myself with them, the sensitiveness in the blue and violet is the difficulty.

But whilst such a special plate as I describe would be warmly welcomed, we must not forget that the proved goodness of the photographic star-images of what may be called violet refractors, *i.e.* refractors corrected so that the minimum focus is for violet light, is in great measure to be attributed to the fact that light of short wave length is used. The increase in the diameter of star-images with increased exposures or great brightness of the star, may be, as Scheiner has lately suggested, due to defects in the mode of support of the object-glass or mirror, but doubtless the *goodness* of the images with proper exposures must be connected with the smallness of the scale of the diffraction pattern, and with the concentration of light to the centre of the pattern, which may be got at smaller expense with a violet refractor than with a visual.

Probably few astronomers would have been bold enough, if no photographic plates had been available except plates sensitive only to yellow and green, to urge the preparation of plates sensitive in the violet, on the ground that a violet refractor would give much better results, because short wave lengths were used. And yet a comparison of the results obtained with violet refractors and with reflectors would lead one to the view above expressed, and, I believe, generally accepted.

The increased *range* of sensitiveness of modern photographic plates, with respect not only to the colour, but also to the intensity of the light affecting them, is all in favour of the reflector. A greater and more desirable advance than even the preparation of plates to suit visual telescopes would, I think, be made if the difficulties of supporting, adjusting, and maintaining a mirror were overcome; so that the measurement of star-images may be regarded with as much confidence in the case of plates exposed in reflectors as in refractors. H. F. NEWALL.

Madingley Rise, Cambridge, September 25.

Hering's Theory of Colour Vision.

I AM very much surprised to see that Prof. Ebbinghaus, in the last number of the *Zeitschrift für Psychologie*, announces as new a discovery which has a critical bearing upon Hering's theory of colour-vision—the fact, namely, that two grays composed the one of blue and yellow, and the other of red and green, and made equally bright at one illumination (by admixture of black with whichever of them turns out to be the brighter), do not continue to be equally bright at a different illumination. If two complementary colours were purely antagonistic—that is, if the colour-processes simply destroyed each other, as processes of assimilation and dissimilation must do, and if the resulting white was solely due to the residual white which accompanies every colour and gives it its brightness, then the relative brightness of two grays composed out of different parts of the spectrum could not change with change of illumination. The fact that they do change is therefore completely subversive of the theory of Hering, or of any other theory in which the complementary colour-processes are of a nature to annihilate each other. This consequence of the fact, as well as the fact itself, I stated at the Congress of Psychologists in London in August, 1892, and it was printed in the abstract of my paper, which was distributed at the time, and also in the Proceedings of the Congress.

Prof. Ebbinghaus' discovery is apparently independent of mine, for he supposes that the phenomenon cannot be exhibited upon the colour-wheel. This is not the case; with fittingly-chosen papers (that is, with a red and green which need no addition of blue or yellow to make a pure gray, and with a corresponding blue and yellow) it is perfectly evident upon the colour-wheel. The same paper circles which I used to demonstrate it in Prof. König's laboratory in Berlin are, at the request of Prof. Jastrow, now on exhibition at the World's Fair at Chicago. While Prof. Ebbinghaus' discovery of the fact is therefore doubtless independent of mine, I allow myself to point out that mine is prior to his in point of time.

Baltimore. CHRISTINE LADEL FRANKLIN.

"Megamicros."

IN NATURE of August 24 the following extract from the *Bulletin de l'Académie de Belgique*, No. 6 (1893), is given, viz.:—

"According to Laplace, if the dimensions of all the bodies of the universe, their mutual distances and velocities were to increase or diminish in a constant proportion, these bodies would describe the same curves as they do now. The appearances presented to observers would be the same, and independent of the dimensions assumed. Hence the only facts we are able to appreciate are ratios. In opposition to this theorem, M. Delbœuf shows that if a system consisting of the sun and earth were to be diminished in linear dimensions to one-half, all densities remaining the same at homologous points, and the orbital velocity of the earth were reduced to one-half its value, there would be certain changes in the relations of an observer to his surroundings which could not escape notice. The velocity of sound propagation would be the same as before, but the distance traversed during a certain number of vibrations will appear larger," &c. (p. 406 of NATURE).

Here it seems to be overlooked that according to the above system of reduction of scale, the molecules of air which propagate sound would have to be conceived as diminished in size correspondingly with the planets, earth, &c., for if not, obviously the constancy of ratio of relative dimensions supposed by Laplace could not persist under this reducing process. For, considering "all the bodies in the universe," we cannot regard the linear dimensions of the earth and larger bodies as reduced to one-half, and neglect the smaller bodies (molecules). If then the dimensions of the molecules of air, and also their normal velocities be supposed reduced to one-half, then (according to what is set forth in a paper of mine in the *Philosophical Magazine*,[1] June 1877, relating to sound), the velocity of sound would be exactly halved, and therefore not remain "the same as before," as M. Delbœuf supposes. But the velocity of sound would *appear* the same as before to us with our halved standards of length on the reduced planet, in accord with what Laplace states. For as indicated in the above paper (*Phil. Mag.*), "The velocity of propagation of a wave—such as a wave of sound—in a gas is solely determined by, and proportional to, the velocity of the molecules of the gas; and the velocity of propagation of the wave is not affected by density, pressure, or by the specific gravity of a gas, or by anything else excepting the velocity of its molecules" (p. 452.)

For, on the Kinetic theory, the molecules of a gas can evidently only act upon each other by direct impact, and they therefore propagate any wave at their encounters at a rate proportional to that at which the molecules are moving in the normal state of the gas. If, we imagine then, the velocities of the smaller bodies (such as the molecules of air) to be halved, just as those of the planets, &c., are supposed halved, then the velocity of sound will be necessarily reduced to one-half, as we have seen.

Hence the above argument based on the Kinetic theory of gases would apparently support Laplace's view; and so the velocity of sound would seem to us precisely the same as before. The distance traversed during a certain number of vibrations would not then (as M. Delbœuf thinks) appear larger; all his conclusions seem to me invalidated by his assumed *unsymmetrical* selective diminution of sizes. Of course one-half the present metre would on the reduced earth be still called a "metre," because it would be a ten-millionth of the earth's quadrant, as now. A man a metre high would still be a metre high in the planet of reduced size, and the metre standard he grasped would still be the same length as himself. So it appears that if the universe known to us were suddenly halved in size by reducing the linear dimensions and velocities of all the bodies to that extent, there would be nothing to allow the change to be detected. This would also seem to harmonise with the Spencerian doctrine of the Relativity of all knowledge.

Hamburg, September 4. S. TOLVER PRESTON.

EARLY ASTERISMS.[2]

II.

AS in Egypt so in Babylonia, for the first references to the constellations we must study the religion and the mythology; Jensen shows that the first notions of the Babylonian constellations are to be got by studying the sun-gods, and especially the mythic war between the later sun-god Marduk and the monster Tiāmat.

[1] "Mode of the Propagation of Sound and the Physical Conditions which determine its Velocity on the Basis of the Kinetic Theory of Gases."
[2] Continued from p. 440.

So far as I have been able to gather, any myth like t Egyptian myth of Horus involving combats between t sun and circumpolar star-gods is entirely lacking Babylonia, but a similar myth in relation to some of t ecliptic constellations is among the best known.

In my references to the myth of Horus I have sho that in all probability an astronomical meaning is th the rising sun puts out the northern stars; and there evidence that we have a reference also to a sun-worshippi race abolishing the cult of Set representing the northe stars. I have also shown that temples built to northe stars have had their axes blocked to prevent the worsh and that the northern temples at On and Denderah we among the first founded for the worship of the Divi dynasty of Set or Anubis.

This being so, it is of importance to discuss the Bab lonian myth of the battle between Marduk and Tiām from the astronomical point of view, but before we this it will be well to see if one can trace the history the sun-god of Eridu, which city is universally conced to have been the original centre of Babylonian ide until the descent of the Northmen, and to have be founded by a colony from some other country.

The Sun-god of Eridu.

Let us assume that the earliest sun-god traced Eridu was the sun-god of those early argonauts wh founded the colony.

We are told that this sun-god was the son of Ía ar Dam-kina, his wife symbolising the earth, and that h name was Tammuz (Sayce, p. 144).[1]

This Ía was such a great god that to him was assigne the function of Maker of Men; he was also a great pott and art workman (p. 293), a point I shall return to pr sently. He eventually formed a triad with Anu and B that is, the poles of the heavens and the equator. Th Tammuz (Dumazi) was afterwards identified with Nin Girsu, and ultimately became "the Nergal of Souther Chaldæa, the sun-god of winter and night, who rule like Rhadamanthos, in the lower world" (Sayce, p. 245 and as lord of Hades he was made son of Mul-lil (Sayc p. 197).

This was at first. But what do we find afterwards?

Nergal is changed into the Midsummer Sun! (Jensen p. 484). And finally he is changed into the Spring Su Mardukat Babylon (Sayce, p. 144) where he is recog nised as the son of Ía and Duazag, that is the Easter Mountain (Jensen, p. 237).

Now however difficult it may be to follow these change from the religious point of view, from the astronomica side the changes are not only easily explained, but migh have been predicted, provided one hypothesis be permitted namely, that the colony who founded Eridu were origin ally inhabitants of some country south of the equator.

Such an hypothesis may at first sight appear strange but the view that Eridu was colonised from Cush ha been supported by no less an authority than Lepsius.[2]

Now the boundaries of Cush are not defined, but the may possibly include the Land of Punt from which certainly part of the Egyptian culture was derived.

Punt was always considered a "Holy Land," and i was acknowledged that several of the Egyptian god had been thence introduced. Hathor was "Queen of th Holy Land," "Mistress and Ruler of Punt." Amen R was "Hak" or "King" of Punt, and Horus was th Holy Morning Star which rose to the west (?) of the land of Punt.[3]

Maspero refers to an ancient tradition that the land of Punt could be reached by going up the Nile, where

[1] It would seem also that Isara = Tammuz. This connects the myths o Isis and Osiris, Tammuz and Adonis, and the cult at Byblos (see Sayce p. 228).
[2] Introduction to Nubische Grammatik, 1880.
[3] Rawlinson, ii. 134.

eventually an unknown sea was reached which bathed the land of Punt. Was this one of the great lakes?[1]

Brugsch[2] is of opinion that Punt occupied the south and west coasts of Arabia Felix, but Maspero and Mariette do not agree with him. The two latter authorities identify it with that part of the Somali land which borders on the Gulf of Aden. It is the Cinnamonifera regio or Aromatifera regio of the ancients.[3]

The inscriptions at Dêr el-Bahari make it quite certain that Punt is in Africa. Hottentot Venuses and elephants, to say nothing of the general products of the country referred to as among the freight of the ships on their homeward voyage, distinctly point to Africa, and I think a southern part of it.

The first organised expedition to Punt of which we hear anything is that organised by Se-ānχ-ka-Rā, the last king of the 11th *Theban* dynasty. This was a new traffic by way of the Red Sea. There was then no canal joining the sea with the Nile in existence; the expedition went by land to Coptos.[4]

They further indicate, as Maspero suggests, that the expedition of Hātshepset anchored up a river, and not on the sea-shore, especially since the native huts are shown as built on piles. This again makes Africa much more probable than Arabia.

If we agree that Punt is really in Africa south of Somali-land, there is a great probability that the tradition referred to by Maspero is a true one.

There is distinct evidence that Horus, Hathor, and Amen-Rā are worships coming from the south and dealing with southern stars exclusively. With regard to Horus, it is necessary to discriminate, since there were two distinct gods—Horus in N. and S. Egypt, *and Horus of the south was the elder of the two*. The Hawk God of Edfû, Harhouditi, the southern Horus, had for servants a number of individuals called Masniou or Masnitiou = blacksmiths. The Hawk God of the Delta, the northern Horus, Harsiisit, has for his entourage the Shosou Horou.

Now Maspero has recently pointed out[5] that the southern Horus may have been imported, not from Arabia Felix or Somali-land, but from Central Africa!

Among all early peoples the most important times of the year must necessarily have been those connected with seed time and harvest at each locality. Now the spring equinox and summer solstice south of the equator are represented by the autumnal equinox and the winter solstice to the north of it. If the colonists who came to Eridu came from a region south of the equator, they would naturally have brought not only their southern stars, but their southern seasons with them; but their springtime was the northern autumn, their summer solstice the northern winter. This could have gone on for a time, and we see that their great sun-god was the god of the winter solstice. Tammuz = Nergal.

But it could only have gone on for a time, the climatic facts were against such an unnatural system, and the old condition could have been brought back by calling the new winter summer, or in other words making the winter god into the summer sun-god, in short, changing Nergal into a midsummer sun-god. This it seems they did.

But why the further change from Nergal to Marduk? Because the northern races were always tending southwards, being pushed from behind, while the supply of Eridu culture was not being replenished. The religion and astronomy of the north were continually being strengthened, and among this astronomy was the cult of the sun at the vernal equinox, the springtime of the northern hemisphere, sacred to Marduk. Nergal, therefore, makes another stage onward and is changed into Marduk!

[4] Rawlinson, ii. 131. [5] "L'Antropologie," 189-, No. 4.

It is also interesting to find that in Ninib, another sun god, we have almost the exact counterpart of the Egyptian Horus. He is the eastern morning sun, the son of Isara (? Osiris), and the god of agriculture.[1]

I append one out of many published hymns to the Sun God:—

O Sun (god)! on the horizon of heaven thou dawnest,
The bolt of the pure heaven thou openest,
The door of heaven thou openest.
O Sun (god)! thou liftest up thy head to the world;
O Sun (god)! thou coverest the earth with the majestic brightness of heaven.

Marduk then, the son of Ea, was finally as definite a spring equinox sun-god as Amen Rā in Egyptian mythology was a summer solstice sun-god.

Marduk was more than this, he represented the constellation of the Bull. Here I quote Jensen (p. 315).

"It has already been suggested that the Bull is a symbol of the Spring-Sun *Marduk*; that he was originally complete; that he at one time extended as far as the Fish of *Ia*, *i.e.* the western Fish; that the Fish of *Ia*, out of which the sun emerged at the end of the year in ancient times to enter Taurus, is to represent *Ia*, the God of the Ocean, out of which his son *Marduk*, the early sun, rises daily; finally, that a series of constellations west of the Fish(es) is intended to represent symbolically this same ocean. *Marduk* is on the one hand, as early sun of the day (and the year), the son of *Ia*, the god of the world-water."

As to the sun-god Marduk, then, he represents the sun at the vernal equinox, when the sunrise was heralded by the stars in the Bull.

But what, then, are the fish of *Ia* and the other constellations referred to? They are all revealed to us by the myth. They are the southern ecliptic constellations. We gather this from Jensen's account of the fight that Marduk—this Egyptian Horus—has with certain monsters inhabiting the world-ocean. The monsters being called generically Tiāmat.

Tiāmat.

Tiāmat, according to Jensen, means initially the Eastern Sea (p. 307). This was expanded to mean the "Weltwasser" (p. 315), which may be taken to mean, I suppose, the origin of the Greek ὠκεανὸς, and possibly the overlying firmament of waters.

These firmamental waters contain the southerly ecliptic constellations, the winter and bad-weather signs—the Scorpion, the Goat-fish, and the Fish among them.

It must be pointed out that these southerly constellations were associated with the winter solstice Sun-God of Eridu *in his first stage*.

The Myth of Marduk and Tiāmat.

But this Horus no longer smites the hippopotamus, that is the northern stars, his quarry is elsewhere; he does battle against this world-ocean in the form of Tiāmat and among the allies of Tiāmat we find a Scorpion-Man (p. 277), a Goat-Fish, and a Fish-Man, and to the west of the vernal equinox, *i.e.* in the 'water-region' of the Heavens, a Fish (Fish of *Ia*), a goat-fish and a scorpion.

We are evidently dealing here with Scorpio, Capricornus and Pisces, the ecliptic constellation of the winter months. Marduk against Tiāmat was the never-ending battle of May against December.

Imprimis then we have the later developed northern spring sun destroying the evil gods or spirits of winter, and chief among them, of course, the goat-fish, which, from its central position, would represent the winter solstice.

But this goat-fish was Ia of Iridu. The primal god of

[1] Jensen, p. 195, 198.

Babylonia! This Jensen, by his wonderful analysis (would that I could completely follow it in its marvellous philological twistings, pp. 73-81) puts beyond question, and clinches the argument by showing that our "tropic of Capricorn" of to-day, the goat still represented on our globes of to-day with a fish's tail! was called by the Babylonians "the path followed by Ia" or in relation to Ia.

The myth, then, has to do with the fact that the winter sun worship of Eridu was conquered by the spring sun worship of the north.

If we accept this we can compare the Egyptian and Babylonian myths from the astronomical point of view in the following manner, and a wonderful difference in the astronomical observations made as well as in the form, though not in the basis, of astronomical mythology in Egypt and Babylonia is before our eyes.

Astronomically in both countries we are dealing with the dawn preceding sunrise on new year's day, and the accompanying extinction of the stars.

But which stars? In Egypt there is no question that the stars thus fading were thought of as being chiefly represented by the stars which never set, that is the circumpolar ones, and among them the Hippopotamus chiefly.

The southern cult had conquered the northern one, the southern Horus had conquered Set.

We now learn that in Babylonia the chief change had been in the sun-god. Here the northern cult had conquered. The exotic worship of the winter constellations had been abolished, and they were pictured as destroyed under the form of Tiāmat,[1] although they were once as prominent as Set in Egypt.

Now I believe that it is generally recognised that Marduk was relatively a late intruder into the Babylonian pantheon. If he were a god brought from the north by a conquering race (whether conquering by craft or kraft does not matter), and his worship replaced that of Ia, have we not *mutatis mutandis* the exact counterpart of the Egyptian myth of Horus? In the one case we have a southern sun-worshipping race ousting north-star worshippers, in the other a northern equinoctial sun-worshipping race ousting the cult of the winter solstitial sun. In the one case we have Horus, the rising sun of every day slaying the Hippopotamus (that is the modern Draco) the regent of night; in the other Marduk, the Spring sun-god slaying the animals of Tiāmat, that is apparently the origins of the Scorpion, Capricornus, and Pisces, the constellations of the winter months which formed a belt across the sky from east to west at the vernal equinox.

J. Norman Lockyer.

(*To be continued.*)

THE BRITISH ASSOCIATION.

Nottingham, September 22.

The bright and pleasant weather universally hoped for, but very generally unexpected, has favoured the meeting of the Association after all; it had been the one uncertain element for which the local committee could make no provision. The fine weather has made the success of the gathering complete. By midday on Monday, the 11th, the reception room was in readiness for the multifarious purposes to which it had been applied, and shortly after that time the booking clerks were kept fully employed for some hours in enrolling local members. The arrival of members was less noticeable on Tuesday, but throughout Wednesday the booking clerks, lodging and hotel clerks, the postal department and the various excursion, garden party, and recreation counters were constantly besieged. The admirable writing-room also came largely into use, while the ladies found their way to their own special suite of elegantly furnished apartments. Later on the ladies obtained the privilege of entertaining gentlemen to afternoon tea in their capacious drawing-room, a privilege which became rapidly so popular that the accommodation was inadequate to the demand.

Following the strictly business meetings in the early part of the day, came the first general meeting in the Albert Hall, to hear the President's address. The large hall was comfortably filled with an attentive audience, the decorations consisting of little else than the long series of banners bearing the name, coat-of-arms, and year of service of each of the distinguished Presidents who has passed the chair during the sixty-two years of the Association's existence, the banner of this year's President being suspended in front of his reading-desk. The President's address, which was easily heard throughout the hall, was received with applause, the Mayor of Nottingham and the Bishop of Southwell, respectively proposing and seconding the vote of thanks at its conclusion.

On Thursday (14th) sectional business began in earnest by the delivery of the presidential addresses in the different sections, followed by the reading of papers and reports. The workers of the Association easily found their appointed quarters, and reached them in every case in a few minutes after leaving the reception room, since all the sectional rooms were within easy distance. Five sections met in the University College itself; one in the Poor Law Offices, opposite the College; another in the Central Hall, nearly facing the college; while the geographers had only to pass from the large hall of the Mechanics' Institution (the reception room) to the lecture hall of the same institution. Each of these sectional rooms was completely fitted with all that was requisite to illustrate the papers which were communicated, the equipment ranging from the blackboard and chalk only, to the supply of dark blinds, and lantern supplemented by large diagram frames, electric current, gas, water, compressed gases, and the many other requisites for the experimental sciences. Bearing in mind the difficulty which hard-working members have found at previous meetings in staving off starvation at the luncheon hour, a large luncheon buffet had been provided in the University College; this was accessible to all members, and entailed only a few minutes' absence for luncheon from the business of any section. In the afternoon, Sir John Turner, a local vice-president of the Association, entertained a large party of visitors, with their hosts, in his beautiful grounds at Mapperley; and in the evening the Mayor received the members in the Castle Museum building, where the extensive galleries had been hung with a specially selected series of pictures, and music and refreshments were provided.

Friday (15th) was perhaps specially noticeable for the brilliant demonstration given in Section B by Dr. Meslans, assistant to M. Moissan. The section was crowded, and the audience included a considerable number of the leading British chemists. Dr. Meslans, who had carefully rehearsed his experiments in the laboratory on the previous day, proceeded to prepare gaseous fluorine, and amidst the greatest enthusiasm, both of the experimenter and of his audience, sulphur, phosphorus, silicon, and charcoal were ignited in the stream of the element. Several chemists who entered the room sceptical of the true isolation having been effected, rose and gave their entire assent, and at the suggestion of Sir Henry Roscoe, the President, immediately dispatched a congratulatory telegram to M. Moissan, who had been detained in Paris by indisposition. In the afternoon one party of members

[1] There seems to be no question that Sit, Tiāmat, and the "Great Dragon" of the Apocalypse, represent the same idea. See Sayce, p. 102.

was entertained in the beautiful grounds of Clifton Hall, by Mr. and Mrs. H. R. Clifton; another party was similarly entertained by Mr. and Mrs. Leavers, and inspected the carefully protected rock-dwellings in the grounds. Members met once more in the evening in the Albert Hall, to listen to Prof. Smithell's description of his recent researches on "Flame," and to witness the beautiful experimental demonstration of his views. The audience, at the invitation of Dr. Emerson Reynolds and of Prof. H. B. Dixon, heartily expressed their appreciation of the eloquent discourse, and of the uniformly successful and admirably contrived experiments.

Saturday was in most Sections a *dies non*, as far as scientific work was concerned. Full advantage, however, was taken of the excursions which had been organised for the recreation of the visitors. Sherwood Forest, Haddon Hall, Buxton, Burleigh, Southwell, Minster, Lincoln, Belvoir Castle, and Donington Park were visited in gloriously fine weather; and the list of the places of interest visited was only reduced by one—Wollaton Colliery—this omission being rendered necessary by the strike of the colliers. It may be mentioned that some slight inconvenience had been caused by this lamentable occurrence. Visitors to the town found the military quartered in the neighbourhood of the Guildhall, and learned to their dismay that country houses in which they were to be entertained as guests were filled with billets of police. The railway companies had also been compelled to take off some of their trains; but the inconvenience was scarcely felt—town houses were thrown open to the would-be country guests; trains which would not affect the travelling of members were those selected for removal; and the military parading the streets added a picturesque and entirely peaceful element to the ordinary population of the town. No trouble arose from the miners themselves, although they occasionally solicited alms and food; and it may be stated with truth that visitors to the meeting suffered no more serious loss and inconvenience than that arising from the withdrawal of the permission to descend the colliery. In the evening Prof. Vivian Lewes lectured upon "Spontaneous Combustion," in "The Tabernacle," to an audience of over a thousand working men, who took it into their own hands to accord him a hearty and well-deserved vote of thanks; a similar compliment to the chairman, Dr. Burdon-Sanderson, brought the meeting to a close. Meanwhile a brilliant and crowded audience was listening in the Albert Hall to the concert given by the Sacred Harmonic Society.

"Association Sunday" was marked by the pulpits in many places of worship in the town being occupied by distinguished preachers; amongst these may be mentioned the Bishop of Southwell, Dr. Bonney, Dr. Clifford, Rev. C. Gore, and the Rev. R. F. Horton. By many members the day was, however, spent in the country, or devoted to small social gatherings.

Monday saw the recommencement of serious work in all the sections, relieved later in the day by a garden party at Wollaton Hall, the seat of Lord Middleton, and by an entertainment provided at their Basford Gas Works by the Gas Committee of the Corporation of Nottingham. In the afternoon the General Committee of the Association decided on meeting at Ipswich in 1895. Bournemouth had also applied for the honour of receiving the Association, and announced their intention of renewing their application year by year until they met with success. Application from Toronto was favourably viewed, and it was considered probable that it would be accepted for a future year. The Marquis of Salisbury was elected as President for the meeting at Oxford next year, commencing on August 8, and the other officers of the Association were re-elected. In the evening the Mayor entertained the President, Sectional Presidents, Secretaries, and Treasurer of the Association, together with a few friends, at the Exchange, to dinner; the evening concluded by the lecture given by Prof. Victor Horsley, on "The Discovery of the Physiology of the Nervous System." The lecture was illustrated by a series of original lantern-slides, and was well received by a large and somewhat professional audience, who expressed their thanks, at the suggestion of Prof. Schäfer and Sir Robert Ball.

Tuesday was the only day of the meeting which opened with doubtful weather, inclined to being cold and showery. The unfortunate change culminated in the afternoon at the time of the large garden party in the Arboretum, and had the effect of thinning the attendance to some extent. Those who were present, however, found shelter from slight passing showers in the large tent which covered in the show of the Horticultural Society, and in the capacious refreshment-room; from both of these places the admirable music of the Royal Artillery band could be distinctly heard. The Committee of Recommendations, at their meeting in the afternoon, found it necessary to be economical in the grants made for research; the enrolment of 1661 members had produced only £1653, and this sum was less than that usually received. The list of money grants, however, which were recommended and were finally approved by the General Committee on the following day represent a total of £705. A reception at the Castle Museum brought the day to a close. Mr. Alderman Goldschmidt and Mr. Joseph Bright, as chairman and vice-chairman, respectively, of the Executive Local Committee, received the company. Entertainment was afforded by the string band of the Royal Artillery, and a series of interesting scientific objects were on exhibition. A special feature was the glass-blowing by Herr Zitzmann, of Wiesbaden, who had throughout the week displayed his skill in imitating old Venetian glass-work and in making glass scientific apparatus to large audiences in the chemical theatre of the University College.

The comfort of those attending the *conversazioni* and other general gatherings was secured in great measure by the membership being only an average one, and not unduly large. A larger membership would not only have added to the difficulties of the stewards, but also to the discomfort of those who attended the meetings. It may be safely asserted that the success of the work of the Association in no way suffered by the numbers not being large; whilst those who were playing the part of hosts in the town could the more readily cope with the demand on their kindly services. The number of official and other important members of the Association privately entertained reached nearly 400; and there remained some room both in private houses and in lodgings and hotels, so that the overcrowding frequently complained of in these gatherings was absent.

Of distinguished scientific men from different parts of our own country there was a good attendance; and amongst eminent foreigners who accepted the invitation to attend were the following:—Baron von Reinach; Dr. Meslans, Paris; Prof. Iddings, Chicago; Mons. A. Gobert, Brussels; Prof. Heger, Brussels; Mons. Gilson, Belgium; Dr. Brögger, Norway; Dr. Bock and Dr. Bohr, Copenhagen; Dr. Hertwig, Munich; Dr. Hildebrand, Stockholm; Dr. W. Einthoven, Leyden; Dr. Rothpletz, Munich; Dr. Mandello, Budapest; Dr. Renard, Gand; Mr. Cope Whitehouse, New York; M. de Liegeard, Paris.

On Wednesday little sectional business was transacted, except by the energetic geologists of Section C. In the afternoon the General Committee passed the awards of money towards scientific research, a list of which was given last week.

The business of the meeting was then brought to an end at the concluding meeting by the usual votes of thanks.

In the evening over a thousand members were entertained by the local committee in the Theatre Royal, and witnessed Mr. Wilson Barrett's company in the new play *Pharaoh*.

The concluding day, Thursday, was devoted to whole day excursions to "The Dukeries" (Sherwood Forest, Welbeck, Clumber, Thoresby, &c.), the Midland Railway Works at Derby, Chatsworth and Haddon, Charnwood Forest, Dovedale, Castleton, Matlock and Miller's Dale. The weather was all that could be desired, and the complete organisation led to everything passing off punctually and without a hitch.

The generally expressed opinion of the departing guests was that no meeting was comparable to the present one for enjoyment except that at Montreal. The workers seemed to be generally of opinion that in no direction had the gathering been so useful as in the discussions initiated in several of the sections, to which reference has been made in recent numbers of NATURE. Undoubtedly one of the greatest advantages derived by the annual gathering is the meeting of "researchers" from all parts for the interchange of ideas, and the making and renewal of acquaintance one with another. The impression apparently made on all who have been concerned in the meeting is that the British Association is by no means in a declining condition. It is instinct with life, and those of the inhabitants of Nottingham who have felt the vivifying effect of being brought into contact with many of the scientific pioneers of our time, will wish that the Association, which has stimulated their scientific ardour by its presence, may live to benefit other important centres for many years to come.

FRANK CLOWES.

NOTES.

IT is announced that the bust of the late Prof. John Marshall, which has been subscribed for as a memorial to him, will be handed over to the Council of University College on the occasion of the introductory lecture, by Mr. Bilton Pollard, at the opening of the session on Monday, October 2.

M. JANSSEN, writing to M. Bischoffsheim from the summit of Mount Blanc, on September 12, says that the Observatory has been fixed in its place, and all that now remains is to fit up the interior. It is hoped that observations will be commenced this autumn.

WITH much regret we record the death of Mr. Thomas Hawksley, the well-known civil engineer, on Saturday, September 23. Mr. Hawksley had for some years been at the head of that branch of his profession which deals with gas and water supply. It is said that more than 150 waterworks were constructed under his direction, besides a large number of important gasworks. He was born in 1807, and elected a Fellow of the Royal Society in 1878. In 1871 he was chosen as President of the Institution of Civil Engineers, and held that office for two years. The Institution of Mechanical Engineers elected him President in 1876-7, and he was the first President of the Gas Institute. In addition to these distinctions Mr. Hawksley possessed a number of decorations conferred upon him by various Sovereigns for services to science and to themselves. At the ripe old age of eighty-eight he passed away, leaving behind him a name which will be honoured for many years to come.

THE Right Hon. Lord Thring will, on Tuesday, October 3, distribute the prizes to the successful students of the Medical School of St. Thomas's Hospital. The distribution will take place at three o'clock, in the Governors' Hall.

AT a meeting of the Committee of the Sunday Society, at the Prince's Hall, on Tuesday, the date of Museum Sunday this year was fixed for November 26, when, as in November last, addresses are to be delivered in support of the Society's object, viz. the opening of museums, art galleries, and libraries on Sundays.

PROF. H. A. NICHOLSON will commence the Swiney Lectures on Geology on Monday, October 2, at the South Kensington Museum. His subject is "The Bearings of Geology on the Distribution of Animals and Plants."

THE Gilchrist trustees have granted the delivery of a course of science lectures at the Great Assembly Hall, Mile End Road, on alternate Thursdays, beginning this evening, when Prof. V. B. Lewes will discourse on "Our Atmosphere and its Relation to Life." The other lecturers will be Sir Robert Ball, Prof. Fleming, Rev. Dr. Dallinger, Dr. R. D. Roberts, and Dr. Andrew Wilson. The course will be in connection with the Bethnal Green Free Library.

A COURSE of twelve educational lectures on the principles of Commercial Geography applied to the British Empire will be delivered by Dr. H. R. Mill, at the London Institution, on Tuesday evenings, commencing on October 3. At the opening lecture, which is free, the plan of the course will be explained. Mr. H. J. Mackinder will follow Dr. Mill with a course on the relations between History and Geography.

THE following lectures will be delivered at the Royal Victoria Hall, Waterloo Bridge Road, during October:—"The Life and Work of Sir Richard Owen," by A. Smith Woodward; "A Total Eclipse of the Sun," by Prof. Thorpe; "Electrical Fishes," by Dr. W. D. Halliburton; and "The Compass in Iron Ships," by Prof. Reinold.

THE Dublin Water Committee has recently been carrying out experiments in rain-making. On the 20th inst. three dozen distress signals and one dozen rockets were fired into the air, and ten pounds of tonite were exploded on the ground. A copious fall of rain occurred shortly afterwards, especially on that part of the watershed between the Djouce and the Sugar Loaf Mountains. Whether the precipitation was directly caused by the fireworks is, however, a matter of opinion.

THE weather in these islands has recently undergone considerable change, owing principally to a deep depression which for several days lay between the Shetlands and Norway, causing northerly gales in Scotland, and snow in the northern parts of the kingdom. Frosts have occurred at night over Scotland and the central parts of England and Ireland, while in many places the daily maxima have fallen below 50°. Rainfall exceeding an inch in the twenty-four hours has occurred at several stations in Scotland, but in the midland and southern parts of England the weather generally has continued very dry. From the commencement of the year there is a deficiency in the amount of rain in all districts, amounting to nearly seven inches in the midland counties and south-west of England, and to more than nine inches in the west of Scotland.

THE Rev. S. Chevalier, S.J., Director of the Zi-Ka-Wei Observatory, has recently read a paper before the Shanghai Meteorological Society on the *Bokhara* typhoon which occurred in October, 1892. The typhoon originated on the 7th of October to the east of Luzon, and on the 10th passed very near to the south Cape of Formosa and, whilst crossing that island, wrecked in one night the Norwegian steamer *Normand* and the Peninsular and Oriental steamship *Bokhara*. Observations have been collected and collated for the whole area which came under the influence of the storm, and diagrams are given for selected stations to show the action of the barometer and the position of the typhoon each day from October 8th to 11th. The author considers that the occurrence of a high barometer cannot be taken as a satisfactory indication of a typhoon, as is sometimes asserted, and he gives considerable attention to testing the relation which existed between the occurrence of a high barometer and the typhoon which followed. The first intelligence of the typhoon reached Shanghai on October 8, when a telegram was received from Manila, dated October 7, reporting it to the south-east of Luzon. Mr. Chevalier is of opinion that the typhoon was situated to the north-east, and not to the south-east of Luzon, and he adds that the *Bokhara* left Shanghai with inaccurate information. The storm apparently had its centre about sixty-five miles to the north-east of Appari at 2 p.m. on the 9th, and it must have travelled directly towards the south Cape of Formosa, being about 130 miles distant at 9 p.m. At that time the *Bokhara* was outside the Channel, and had not yet entered into the gale. From the quick fall of the barometer and the veering of the wind from north-east to south-west in a few hours, it is evident both that the centre had passed very near the Cape, and that it had recurved towards the north and north-east, instead of continuing to the north-westward. The barometer on board the *Bokhara* when at its lowest was 29·15 inches, where it remained for several hours. On the evening of the 10th the vessel was quite unmanageable owing to the heavy wind and sea, and was cast on the reef before midnight. The paper contains much valuable data relating to the violent storms which occur from time to time in the China seas.

THE detection of particular pathogenic bacteria in water in the presence of numerous harmless water forms, involves the use of special methods requiring much care and skill in their application. Koch (*Zeitschrift für Hygiene*, vol. xiv. 1893) recently recommended for the isolation of the cholera organism in water the addition of one per cent. of peptone and one per cent. of common salt to 200 c.c. of the water under examination. The latter ingredient is added on account of Dunham's discovery that the cholera bacilli multiply very rapidly when more salt than usual is added to the culture material. The treated water is then incubated at 37° C. for periods of ten, fifteen, and twenty hours, and agar-plates poured at these several intervals, whilst a careful microscopic examination is made of the surface of the liquid. Any colonies resembling those of the cholera organism are isolated from the agar-plates, and are further tested for the indol reaction, as well as for the pathogenic action on guinea-pigs. Koch states that by means of this method he was able to identify the cholera bacillus in a number of waters submitted to him during the recent cholera epidemic in Germany. Quite recently another modification has been published by Arens, "Ueber den Nachweis Weniger Cholerakeime in gröszeren Mengen Trinkwassers." (*Münchener med. Wochenschrift*, 1893, No. 10.) The suspected water is first rendered distinctly alkaline by the addition of 1–1·6 c.c. of a ten per cent. solution of caustic potash to 200 c.c. of the water, so that the latter contains ·05–·08 per cent. of KOH. This alkalised water then receives pancreas bouillon in the proportion of one to nine parts of the water. This bouillon is composed of broth obtained from the pancreas to which Witte's peptone is added, and the whole neutralised with carbonate of soda until a highly diluted portion yields a faint red colour with rosolic acid. The treated samples of water are then incubated and examined as described above. Arens claims that by means of this method cholera bacilli can be detected when present in such small numbers as 2 in 5 c.c. of water.

Two official maps of the geology of parts of Germany have been recently published; one of them, "Geognostische Uebersichtskarte des Königreichs Württemberg," has a scale $\frac{1}{600000}$. The strata are delineated with great minuteness, the subdivisions shown by colour and signs being as follows: 8 Quaternary, 10 Tertiary, 4 Cretaceous, 11 Jurassic, 18 Triassic, 4 Permian, 1 Carboniferous, 1 Devonian (?), 1 Archæan, 6 Igneous. The other map, "Geologische Uebersichtskarte von Elsass-Lothringen," by E. W. Benecke, has a scale $\frac{1}{500000}$. Although on a slightly larger scale, this map shows fewer subdivisions of the sedimentary series than does that of Württemberg; the crystalline rocks of the Vosges, &c., with their associated serpentines and limestones, are, however, carefully drawn. The low price at which these maps are sold is noteworthy—Elsass-Lothringen, 1 mark; Württemberg, 2 marks.

PROFESSOR CHARLES V. RILEY has reprinted, from the Third Annual Report of the Missouri Botanical Garden, the results of his observations, which have now extended over a period of twenty years, on the Pollination of *Yucca*. Every known species of *Yucca* is absolutely dependent, for its fertilisation, on the visits of a single species of insect, in all cases a species of *Pronuba*, a genus of small white moths belonging to the Tineina. The pollen cannot reach the stigmatic tube without artificial aid. The species which has been chiefly observed is *Yucca filamentosa*, which is pollinated by *Pronuba yuccasella*. The process is described in detail by which the female moth pierces the ovary, and deposits the egg in close proximity to an ovule. As soon as the ovipositor is withdrawn the moth runs up to the top of the pistil and thrusts the pollen, which she has gathered from other flowers of the species, into the stigmatic opening, and cross-fertilisation is secured. The larva is developed within the ovary, but the number of ovules destroyed in an ovary is never large, and does not practically affect its fertility. Every other species of *Yucca* has its own special fertilising species of *Pronuba*. *Y. filamentosa* is also abundantly visited by another moth, very similar in appearance to the *Pronuba*, the "bogus *yucca* moth," *Prodoxus decipiens*, which is apparently perfectly useless, and is not dependent on the fertilisation of the ovules for its subsistence. The paper is illustrated by ten plates, and concludes with a monograph of the three known species of *Pronuba* and the ten known species of *Prodoxus*, all named by Prof. Riley.

THE decomposition of any form of energy into two factors, one of which is of a constant magnitude, introduces certain simplifications into the theorems of thermodynamics and chemical physics which appear to merit some attention. Herr W. Meyerhoffer, in the *Comptes Rendus*, points out that the constant factor in the case of heat is not the entropy, as maintained by M. Le Chatelier, but the absolute specific heat, which has the dimensions of an energy divided by degrees of temperature. Entropy, on the other hand, is an energy divided by a number representing the number of degrees possessed by the heat at the time of its passage, and which Herr Meyerhoffer proposes to call the number of the isothermal. The confusion between entropy and absolute specific heat arises from the fact that the dimensions of temperature are at present unknown. Herr Meyerhoffer proposes to call the two factors of energy capacity and potential respectively. Then every transfer of heat will involve a change of two potentials, and the criterion of a reversible process will be the inequality of the two potentials. All the cycles invented since Carnot have always had the same function of transforming the variation of one potential into that of another of different nature. By means of this division of energy, most of the known stœchiometric laws can be reduced to one, thus:—The smallest particles of matter have, in a comparable state, the same capacity of energy. By going through the various forms of energy, Regnault's law concerning the specific heats of gases, and the laws of Dulong and Petit, Faraday, Eötvös, and Dalton may be severally obtained.

Mr. John Daniel has sent us an advance-proof of a paper on "Polarization, using a thin Metal Partition in a Voltameter." The investigation had its starting-point in an observation of Dr. L. Arons', who noticed that ordinary gold leaf, used as a partition in an H_2SO_4 voltameter, allowed a current of ·2 or ·3 ampere to pass without any visible development of gas upon the metal, which was pasted over a hole $1\frac{1}{2}$ c.m. in diameter, bored in a glass plate. The glass plate slid in grooves in a wooden frame, which was placed in the middle of the glass-voltameter. When platinium-foil (0·1 mm. thick) was substituted for the gold-leaf, there was a profuse escape of gas from the metal partition. Mr. Daniel has made similar experiments with partitions of gold, silver, aluminium and platinum of various thicknesses, and with various electrolytes, and has obtained for the different substances, values of the "critical thickness" above which polarization at the partition takes place, as well as some other interesting facts as to "critical current density," &c. He finds, for instance, that the "critical thickness" in good-conducting solutions of H_2SO_4, $CuSO_4$ and NaCl, is greater than ·00009 mm., but less than ·0004 mm., in the case of gold; while ·00015 mm., and ·002 mm. are the corresponding figures for platinum, with a current density of not more than 0·1 ampere per square c.m. of the metallic partition. Between these "critical limits" the polarisation for a given current increases with the thickness. In $CuSO_4$, all the plates except those below the critical thickness were destroyed by oxidation, and a similar effect was noticed in NaCl, in which gold and silver below the critical thickness were quite unaffected, while above it they could not be used on account of the chemical action.

Notes from the Marine Biological Station, Plymouth.—Last week's captures include the Ascidian *Ascidia mollis*. The tow-nets continue to yield the regular autumn forms, among which the Liphonophore *Muggiæa atlantica* and the larvæ of the Polychæta *Magelona* and *Terebella* have generally been plentiful. An interesting feature of recent tow-nettings has been the presence of numerous minute free-floating colonies of certain Didemnidæ. Young *Echini* and *Asterinæ* of this season's growth are now plentiful at a depth of five fathoms and in coralline tide-pools respectively. The following animals are breeding:—The Hydroid *Sertularella Gayi*, the Nemertine *Amphiporus dissimulans*, the Archiannelid *Histriobdella Homari*, and the parasitic Cirrhipede *Sacculina*.

The additions to the Zoological Society's Gardens during the past week include a Leadbeater's Cockatoo (*Cacatua leadbeateri*) from Australia, presented by Miss Mercy Grogan; a Common Quail (*Coturnix communis*) British, presented by Mrs. Mazelin; two Black-pointed Teguexins (*Tupinambis nigropunctatus*) a Crowned Snake (*Scytale coronatum*), a Tree Boa (*Corallus hortulanus*), a —— Snake (*Leptognathus nebulatus*) from Trinidad, W.I., presented by Messrs. Mole and Urich; two Hamsters (*Cricetus frumentarius*, white var.) European, a Black-headed Caique (*Caica melanocephala*) from Demerara, a Corean Sea Eagle (*Haliætus branickii*) from Corea, a Black-pointed Teguexin (*Tupinambis nigro-punctatus*), a Tree Boa (*Corallus hortulanus*), a Boddært's Snake (*Coluber boddærti*) from Trinidad, W.I., deposited; a Golden Plover (*Charadrius pluvialis*) British, purchased.

OUR ASTRONOMICAL COLUMN.

Nova (T) Aurigæ Spectrum.—In the current number of the *Astronomischen Nachrichten* (No. 3189) Mr. W. W. Campbell communicates his observations of the spectrum of Nova Aurigæ since its reappearance in August. At this time the continuous spectrum was very faint, the spectrum consisted of isolated bright lines, and the three brightest lines had the intensities and positions of the characteristic nebular lines, the result being that the spectrum of this new star was announced to be that of a planetary nebula. That this view has not been universally adopted is shown by Vogel's paper on the same star, and he inclines to the opinion that the bright lines are chromospheric, and that the brightest line is not the nebula line. In the present paper Mr. Campbell has made more visual and long exposure photographic observations of nebular spectra, and finds no less than five other lines which are in the spectrum of the new star. The nebulæ he uses here for comparison are: Orion, G.C. 4390, N.G.C. 7027, G.C. 4964, G.C. 4373, and in the photographs of their spectrum he obtains 12, 12, 7, 10, and 5 lines respectively that appear to him to be new. The tabulated list of lines brings out very clearly, that with the exception of the line 451, the identity of which is uncertain in these nebulæ, the Nova lines are matched perfectly in one or more of them, allowing for the fact that they (the Nova lines) were shifted about five-tenth metres (in August and November, 1892) towards the violet. The Nova spectrum, as Mr. Campbell says, "certainly differs no more from the nebular spectra than the nebular spectra differ from each other." As for the lines, 4857, 4336, 4098, and 396 are the well-known hydrogen lines; 5002, 4953, the first and second nebular lines, while all the others correspond well with the nebular lines. The presence of these four hydrogen lines and the chromospheric line 4472, strengthens, as he says, his argument, and he concludes with the words that "if the spectrum is not conceded to be nebular, I must ask what else we should expect in that spectrum if it were nebular?"

The Fireball of January 13, 1893.—In the *American Journal of Science* (vol. xlvi. September, 1893), Prof. H. A. Newton contributes a discussion of all the observations that were made of the large fireball that was observed in America in January last. The great interest attached to this fall lay in the fact, as previously mentioned in this column, that Mr. Lewis, of Ansonia, Conn., happened to obtain a very good picture of the trail as it passed in the line of sight of his instrument while he was photographing the comet Holmes. Prof. Newton seems to have taken great pains to have the information as accurate as possible, and has even had some of the observers cross-examined, so to speak, on many particular points. The plate on which the photograph was taken is 4 by 5 inches, and the meteor went nearly centrally across it, the photographed portion being about 19° long. Several stars of the tenth magnitude in the middle, and some of about the eighth, near the margin of the plate, are shown on the negative, so that some fairly good measurements of the position of the track have been procured. The co-ordinates of seven points of the trail have thus been measured, and a very slight curvature of the path is indicated by the results but not clearly proven, the curvature being caused, as suggested by Prof. Newton, by "the atmosphere's resistance of the irregularly shaped body." An enlarged print of the photograph (about 26 inches long) accompanies the paper. The striking feature of it is the irregularities of light on the path, and also its increase in frequency as the end of the plate is reached. This is due, as supposed, to a rotation of the stony mass, "more rapid at the end than at the beginning, and that the unequal amounts of burned material were thrown off according as a well burned or a raw surface was for the instant in front."

NITRO-METALS, A NEW SERIES OF COMPOUNDS OF METALS WITH NITROGEN PEROXIDE.

A remarkable new series of compounds, formed by the direct union of nitrogen peroxide with certain metals, and of a nature somewhat akin to that of the metallic carbonyls recently discovered and investigated by Mr. Mond and his co-workers, are described by MM. Sabatier and Senderens in the September number of the *Bulletin de la Société Chimique*. It was observed that when vapour of peroxide of nitrogen in a state of tolerable purity was allowed to stream at the ordinary temperature over metallic copper, cobalt, nickel, or iron, these metals being in the finely-divided and pure condition obtained by the recent reduction of their oxides by hydrogen, rapid absorption of the nitrogen peroxide occurred with the formation of definite compounds possessing properties of an exceptionally interesting kind. These compounds are solid non-volatile substances, unlike the metallic carbonyls in this respect, and are represented by the general formula M_2NO_2, where M represents either of the four metals mentioned. Their discoverers propose the name *metaux nitrés*, which perhaps may be conveniently rendered into English as *nitro-metals*.

When a quantity of copper, recently prepared by the reduction of copper oxide in the usual manner by means of a stream of hydrogen or of carbon monoxide, is exposed at the ordinary summer temperature (about 25° being the average temperature of the laboratory while MM. Sabatier and Senderens were conducting these experiments) to a current of the reddish-brown vapour of nitrogen peroxide, it becomes rapidly attacked and converted into a brown substance, considerable heat being at the same time evolved and a large proportion of the nitrogen peroxide absorbed. The brown solid substance produced is found to react with great energy with water, the reaction being accompanied by a copious evolution of nitric oxide, NO. At 30° reduced copper absorbs no less than a thousand times its volume of nitrogen peroxide. Upon analysis of the product it is found to contain about 74 per cent. of copper. A compound of the composition Cu_2NO_2 would contain 73·4 per cent. The nitrogen present was also determined directly, by heating with excess of copper in a stream of carbon dioxide, the nitrogen being measured over caustic potash in the ordinary manner; its amount was found to correspond closely with that demanded by the above formula.

In preparing nitro-copper care must be taken to free the nitrogen peroxide from traces of the vapour of nitric acid, for this acid decomposes the compound with energy, effervescence occurring and the green nitrate of copper being produced. To prevent the deleterious effects of traces of admixed nitric acid vapour the red fumes are allowed to pass first through a column of litharge and afterwards over phosphoric anhydride.

Nitro-copper is unalterable in dry air at ordinary atmospheric temperatures. When heated in pure nitrogen it is dissociated, a temperature of 90° being ample to effect the change; nitrogen peroxide is evolved together with smaller quantities of nitric oxide and nitrogen, and partially oxidised copper remains. One of the most useful properties of nitro-copper is that it may be used for the purpose of liquefying nitrogen peroxide; if a quantity is placed in one limb of a Faraday V-tube and heated, the other limb being cooled, the nitrogen peroxide liberated by the dissociation rapidly collects in the liquid form in the cold limb. If the tube is removed and allowed to stand a short time, re-absorption of the peroxide by the copper occurs. Water reacts with nitro-copper as above mentioned with considerable violence, pure nitric oxide entirely soluble in solution of ferrous sulphate being briskly evolved. The aqueous solution contains cupric nitrate and nitrite, and a sediment of pure copper remains. In moist air, therefore, nitro-copper rapidly deteriorates, becoming enveloped in red fumes and its surface turning green. Hydrogen is without action upon it in the cold, but when heated to 180° large quantities of ammonium nitrite and free ammonia are produced. Dry ammonia gas reacts at the ordinary temperature with some energy upon nitro-copper. White clouds of ammonium nitrate and nitrite and of moisture first make their appearance, then suddenly the mass becomes incandescent and more copious clouds of ammoniacal salts and steam are produced, the residue consisting of copper mixed with ammoniacal oxide of copper. Sulphuretted hydrogen likewise reacts at the ordinary temperature with nitro-copper, heat being evolved, water, sulphur, and a blue sulphide of copper being the products of the reaction.

It would thus appear that nitro-copper is of a kindred nature to the metallic carbonyls, the nitrogen peroxide being held in a similar manner to the carbon monoxide of the latter compounds, and capable of being liberated in a regular manner by the dissociation of the compound by heat. The substance may, in fact, be employed as a convenient means of storing nitrogen peroxide, with the certainty of being able to liberate it by a comparatively slight rise of temperature whenever it is desired to procure some for experimental purposes.

Metallic cobalt reduced from its oxide by means of hydrogen at a temperature below redness is only difficultly pyrophoric in air, not becoming incandescent on admission into air with anything like the readiness of iron. It burns energetically in the cold, however, in nitrogen peroxide. When the nitrogen peroxide vapour is diluted with nitrogen, the heat of the reaction is modified, and the formation of nitro-cobalt occurs in a regular manner, as in the case of copper. It is necessary in the case of cobalt to conduct the preliminary reduction in hydrogen in the same tube as is afterwards used for the preparation of the nitro-compound, in order to avoid re-oxidation of the metal, and it is advantageous to employ as low a temperature for the reduction as possible.

Nitro-cobalt is a black solid substance. Its reaction with water is very violent, but less nitric oxide is produced than in the case of nitro-copper. The rose-coloured solution contains mainly nitrate of cobalt, and a quantity of basic nitrite is found amongst the residual copper. When nitro-cobalt is heated in an atmosphere of nitrogen, a small quantity of nitrous fumes are first evolved, then almost immediately violent deflagration, accompanied by a flame of great brilliance, occurs. The same explosive deflagration occurs if, at the end of the preparation, the supply of diluting nitrogen is shut off before the nitrogen peroxide. When mixed with a combustible substance nitro-cobalt forms a dangerous explosive. If a small quantity wrapped in paper is introduced into an eprouvette filled with mercury at the top of which is a little water, a violent explosion at once results upon the arrival of the small paper packet at the surface of the mercury, owing presumably to the heat of the reaction of a portion of the nitro-cobalt with water causing sudden dissociation of the whole, the organic matter of the paper burning in the gaseous products of the dissociation.

Nitro-nickel is more difficult to obtain in a pure state, for cold reduced nickel reacts so vigorously with nitrogen peroxide that even when the latter is largely diluted with nitrogen a partial oxidation of the metal occurs. Actual incandescent combustion is, however, avoided, and a regular absorption of the peroxide vapour occurs. In a careful experiment a product containing 20 per cent. of NO_2 instead of the theoretical 28 per cent. was obtained. Nitro-nickel closely resembles nitro-cobalt; it is a black substance which reacts with water with evolution of nitric oxide, and which deflagrates with explosive force when heated in a current of inert gas.

Nitro-iron is still more difficult to isolate. When the peroxide is diluted with a very large excess of nitrogen, it is quickly absorbed by reduced iron up to a certain point, when the passage of more peroxide invariably brings about brilliant deflagration and consequent destruction of the product. There is ample evidence, however, that iron does form a nitro-compound of a similar interesting nature to that of the nitro-compounds of copper, cobalt, and nickel above described.

A. E. TUTTON.

PHYSICS AT THE BRITISH ASSOCIATION.

SECTION A met in the well-appointed lecture theatre of the Nottingham University College. Mr. Glazebrook had only just finished his presidential address when an incident occurred which was of interest as showing that members meant business, and were not disposed to allow the authority of the chair to be questioned. Perhaps the experimental work communicated was not of striking novelty or importance, but some of the informal communications and discussions—notably those on electrical theory, the connection between ether and matter, and the teaching of elementary physics—were of great interest, especially to teachers of physics. This was largely due to the active part taken by Lord Rayleigh, Profs. Fitzgerald, Carey Foster, Oliver Lodge, Rücker, and other leading physicists. The discussion occasionally tended to resolve itself into an exchange of ideas around the lecture-table, but as the ideas were for the most part interesting (and energetically expressed) members did not appear to object. At first there was an occasional grumble against Dr. Lodge's innovation of starting at 10 a.m., but the wisdom of the change was shown by the fact that the Section had generally to sit until 2 p.m.

At the first sitting on Thursday (September 14), after the President's address, the "Report of the Committee on Solar Radiation" was communicated. Observations have been made with a thermometer enclosed in a non-conducting case, an image of the sun being thrown upon the bulb. Simultaneous readings of screened thermometers within the case were also taken, and the excess of temperature noted from minute to minute. The thermometer has since been replaced by a thermo-junction, which works very sharply, the readings becoming steady in about six minutes, whereas with the thermometer twenty minutes are required. The readings were calibrated by comparison with an iron-copper junction, heated in paraffin oil and balanced against the actinometer couple. 1° F. was found to be equal to about thirty-six divisions. Another Committee gave detailed reports of magnetic work at the Falmouth Observatory. The other Committees submitted formal reports asking for re-appointment, in some cases with small grants of money.

Prof. G. F. Fitzgerald gave an interesting communication on "The period of vibration of Disturbances of Electrification of the earth." The period of oscillation of a simple sphere of the size of the earth, supposed charged with opposite charges of electricity at its ends, would be about $\frac{1}{17}$th of a second; but the hypothesis that the earth is a conducting body surrounded by a non-conductor, is not in accordance with the fact. Probably the upper regions of our atmosphere are fairly good conductors. In a Geissler tube air is a good conductor, and we know that when part of a gas is transmitting an electrical disturbance the rest of the gas in its neighbourhood becomes capable of transmitting such as well. Extending the analogy, we may assume that during a thunderstorm the air becomes capable of transmitting small disturbances. If the earth is surrounded by a conducting shell its capacity may be regarded as that of two concentric spheres, and is accordingly greater than that of a simple sphere, which would produce a corresponding change in the rate of oscillation. But at the same time the presence of currents in the outer air would alter the self-induction; and calculation shows that the net result is a comparatively slight change in the period of oscillation. If we assume the height of the region of the aurora to be 60 miles or 100 kilometres, we get a period of oscillation of 0·1 second. Assuming it to be 6 miles (or 10 km.) the period becomes 0·3 second. On the sun we might expect very much greater periods of oscillation, but these oscillations would not give rise to radiations. If alternating currents of the kind referred to really travelled north and south around the earth they would give rise to east and west alternating magnetic forces of periods between $\frac{1}{10}$ and $\frac{3}{10}$ of a second. Dr. Lodge has already looked for evidence of such magnetic forces, but on the assumption that the period would be $\frac{1}{17}$ second. The author has calculated what magnetic disturbances would be produced by given charges. A disturbance equal to $\frac{1}{10}$ part of the horizontal force of the earth would correspond to an electrostatic charge of 80 C.G.S. units per sq. cm. Such a charge would reduce the superficial pressure on the earth by an amount corresponding to a weight of 40 gm. per sq. cm. This does not sound probable, but we must remember that it would correspond to a most fearful magnetic storm. A charge of 8 C.G.S. units per sq. cm. would produce a variation of $\frac{1}{100}$ of H, and would not sensibly affect the barometer. The records of existing magnetic observatories are not sufficiently complete to admit of testing the other suggestions made in the paper. Prof. O. Lodge thought that the detection and observation of such magnetic disturbances was work that could only be done in a National Physical Laboratory. If the sun were a conducting body surrounded by a non-conductor, the period of an electrical oscillation upon it would be $6\frac{1}{2}$ seconds. He had hung up in his laboratory a needle and watched it for hours, but the only disturbances observed were due to trains and traffic. He pointed out that the electric vibrations of a molecule, calculated from its size, were more rapid than those required to produce light. He suggested the addition of a jacket like that which Prof. Fitzgerald assumed to exist around the earth; but would this prevent radiation?

The Moon's Atmosphere and the Kinetic Theory of Gases.—Sir Robert Ball has suggested that the absence of any atmosphere investing the moon is a simple and necessary consequence of the kinetic theory of gases. Prof. Liveing has applied this theory to interplanetary and interstellar space, with reference to the chemical constitution of planetary atmospheres. According to Sir Robert Ball the mean molecular speed of oxygen and nitrogen is less than the speed with which a body would have to be projected in order to leave the moon without ever returning; but in the course of collisions between the molecules they frequently attain speeds sufficiently great to enable them to overcome the moon's attraction, and thus escape from the moon's atmosphere. On the other hand, the speed required to permanently leave the earth is one which "it would seem that the molecules of oxygen and nitrogen do not generally ever reach," and therefore the earth retains a copious atmosphere. Mr. G. H. Bryan, in reading his paper on this subject, stated that no statistical calculations had hitherto been made with the object of testing these questions; he was not aware until his paper had been printed that explanations based on the kinetic theory had been suggested as far back as 1878 by Mr. S. Tolver Preston and Mr. Johnstone Stoney. Mr. Bryan has applied the theory to investigate that effect of varying temperatures upon the relative densities of oxygen and hydrogen in a permanent distribution under various conditions; he has also calculated the average number of molecules of gas to every one whose speed is sufficiently great to overcome the attraction of given bodies in the solar system, and gives tables showing the results. Thus for oxygen at 0° C., rather over one molecule in every *three billion* is moving fast enough to fly off permanently from the moon, and only one in every $2{\cdot}3 \times 10^{329}$ is moving fast enough to escape from the earth's atmosphere; while the sun's attraction, even at the distance of the earth, prevents more than one in every 2×10^{4910} from escaping. In the discussion which followed, Sir Robert Ball stated that the suggestion really did not originate with himself, but were familiar to him as having been discussed many years ago in a paper by Mr. Johnstone Stoney. Among celestial bodies the moon is unique in having no atmosphere. In the earth's atmosphere there is no free hydrogen. Stoney's theory accounts for these effects. On the other hand, in the case of big bodies like Sirius it is hydrogen, and essentially hydrogen alone, which forms their atmosphere.

Grinding and polishing of glass surfaces.—Lord Rayleigh stated that he had been investigating the nature of these processes, and gave a most interesting description of the results. He first pointed out that the process of grinding with emery is not, as is commonly supposed, a scratching process. The normal effect is the production of isolated detached pits—not scratches. The glass gives way under the emery; at the same time the emery gives way under the glass and suffers abrasion. An image seen through glass which has been finely ground (but not yet polished) has perfect definition. And so when the sun is viewed through a cloud the image is sharp as long as there is an image; even when the cloud thickens, the edge appears to be sharp until we lose the image altogether. A glass lens finely ground gives very good definition, but there is great loss of light by irregular reflection. To obviate this the lens is polished, and examination under a microscope shows that in the process of polishing with pitch and rouge the polishing goes on entirely on the surface or plateau, the bottom of each pit being left untouched until the adjoining surface is entirely worked down to it. It appeared interesting to investigate the amount of glass removed during the process of polishing. This was done both by weighing and interference methods, and the amount removed was found to be surprisingly small. A sufficiently good polish was obtained when a thickness corresponding to $2\frac{1}{2}$ wave-lengths of sodium light was removed, and the polishing was complete when a thickness corresponding to 4 wave-lengths was removed. Lord Rayleigh is of opinion that the process of polishing is not continuous with that of grinding, but that it consists in a removal of molecular layers of the surface of the glass. Grinding is easy and rapid, whereas polishing is tedious and difficult. The action of hydrofluoric acid in dissolving glass was also investigated, and was found to be much more regular—that is, has generally been assumed to be by chemists. It was found to be easy to remove a layer corresponding in thickness to half a wave-length of sodium light; and with due precautions as little as one-tenth of a wave-length.

Mr. W. B. Croft exhibited simple apparatus for observing and photographing interference and diffraction phenomena. No bench was used, but the various pieces of apparatus were mounted on the usual stands used for holding lenses, &c. One of these contained a thin aluminium plate with a needle-hole, or the slit of a spectroscope. On this the light of a lamp was focussed by means of a lens. As an observing eye-piece, the eye-piece of a Beck microscope was used and was placed about 2 ft. from the slit or point, the object being introduced between. The stands should be adjusted so that the light proceeds straight into the eye-piece. The whole of the special apparatus required need only cost a few shillings, and with this the usual phenomena of Fresnel's bi-prism, sharp edges, perforated zinc, &c., can be both seen and photographed. Mr. Croft exhibited an admirable series of slides photographed direct with the aid of his apparatus, including interesting examples of the bright central spot in the shadow of a small opaque screen (shot).

On Sun-spots and Solar Envelopes.—The Rev. F. Howlett gave an account of observations and records made by him during the last thirty years of sun-spots, &c., and stated that he had not on a single occasion been able to verify the assertions made in 1769 by Dr. Wilson with reference to the behaviour (through fore-shortening) of the umbra and penumbra as a sun-spot approaches the limb of the sun.

On Friday a report was submitted "On our Present Knowledge of Electrolysis and Electro-Chemistry." This was part of a report which was being drawn up by Mr. W. N. Shaw and Mr. T. C. Fitzpatrick. Many investigators have been engaged upon electrolytic work, but their observations have been published in scattered papers and expressed in a manner which makes comparison of them difficult. The present instalment of the report is the work of Mr. Fitzpatrick, who has at great pains collected all the available information on the electro-chemical properties of solutions in water and has compiled an exhaustive table showing the different chemical salts in solution. Data are given respecting conductivity, temperature coefficients, migration constants of ions (from which one can calculate the rate at which ions travel through solutions), fluidity (the inverse of viscosity), &c. As with falling objects so it is with ions; they travel more quickly through a limpid fluid than through a viscous one. This is just why acids conduct better than salts.

On the connection between the Ether and Matter:—Prof. O. Lodge made a further report as to experiments made with the same apparatus as that which he had described to the Section at the Cardiff meeting in 1891. Ever since Fresnel's time the question has been debated whether—(1) the earth carries with it the ether in its immediate neighbourhood, thus causing a disturbance, or (2) rushes through it, and it through the earth, each being independent and moving independently. Dr. Lodge has been endeavouring to settle this question by finding out whether a rapidly revolving steel disc (like a circular saw) exercises any drag upon the ether in its immediate neighbourhood. He uses two such discs of tough steel, about a yard in diameter, rotating in parallel planes an inch apart. He is now able to run the discs at the rate of 3000 revolutions per minute; but even at this high speed no effect is observed which can be attributed to any drag of the ether. He has also replaced the discs by an oblate spheroid of wrought iron with a deep channel or groove cut in it and wound with wire; but the rotation of this transversely magnetised mass (weighing about a ton) does not set the ether in motion.

A Mechanical Analogue of Anomalous Dispersion.—Mr. Glazebrook described a mechanical model which he had constructed to illustrate the theory of anomalous dispersion propounded by Sellmeyer, and developed by Helmholtz and Lord Kelvin. The model consisted of rows of balls connected to each other by elastic strings and connected to fixed beams by springs of varying stiffness.

Prof. Fitzgerald communicated a note on Prof. Ebert's method of estimating the radiating power of an atom, and stated that the results show that molecules have a complex structure, otherwise they would radiate very badly. Prof. Fitzgerald holds that the vibration of an atom is the mechanical vibration of a minute bit of the corresponding matter; and that the ionic charges by their corresponding vibrations excite the external radiation.

Lord Rayleigh gave the results of his investigations on the "Theory of Reflection from Corrugated Surfaces," and also, in the absence of the author (Lord Kelvin), read two papers "On the Piezo-Electric Property of Quartz," and "On a Piezo-Electric Pile." These were followed by two interesting communications on electro-magnetic work carried out under the direction of Prof. Hertz in Bonn.

On Electric Interference Phenomena.—Mr. E. H. Barton described experiments on phenomena somewhat similar to Newton's rings, but exhibited by electromagnetic waves in wires. The waves were generated by a Hertzian primary oscillator consisting of two discs of 40cm. diam. each connected by a wire 1m. long to small brass balls between which sparks passed. Opposite these discs, and about 30cm. distant, were two similar ones from which proceeded a pair of parallel copper wires 8 cm. apart and 160m. long. Along these the waves were propagated and the interference phenomena exhibited. The phenomena in question were produced by hanging sheets of tinfoil on the wires for a certain part of their length. Where the sheets hung the capacity and self-induction of the leads were changed, thus causing a partial reflection of the waves from the *beginning* of this *abnormal* part. But a *second* reflection occurs at the *end* of this part also. Thus interference phenomena were set up, and as the length of the abnormal part was gradually increased the intensity of the transmitted waves was found to periodically increase and diminish. Mr. Barton has recently given (Proc. Roy. Soc.) a theory of these phenomena with which the experiments are in fairly good accord.

On the Passage of Electric Waves through Layers of Electrolyte.—The method and apparatus used in this research were described by Mr. G. H. Yule in a communication to the Royal Society in June last, and an experimental curve was given in the same paper showing that the transmission of trains of electromagnetic waves through a layer of distilled water follows the same law as that of light through a thin plate, *i.e.* that the transmitted intensity varies periodically as the thickness of the plate increases. Similar curves were now given, using dilute solutions of zinc sulphate, alcohol, and a mixture of alcohol and water; in all cases the periodic character of the curve was very well marked. As the transmitted intensity attains its first maximum when the thickness of the layer is half a wave-length, the method may be used to determine dielectric constants. That found for water was 69·5, and for 95 per cent. alcohol 26·7—values agreeing roughly with the high values found by previous investigators.

Mr. J. Larmor referred to a familiar type of caustic curve, produced by reflection from a strip of metal bent into circular form. He pointed out that the source of light need not lie in the plane on which the caustic is thrown—the caustic preserves the same form whether the incidence is direct or indirect.

On Saturday the following papers (mainly of mathematical interest) were communicated:—"On a Spherical Vortex," by Prof. M. J. M. Hill; "Note on the Magnetic Shielding of Two Concentric Spherical Shells," by Prof. Rücker; "The Effect of a Long Tube as a Magnetic Screen," and "The Effect of a Hertzian Oscillation on Points in its Neighbourhood," by Prof. Fitzgerald; "The Magnetic Action of Light," by Mr. J. Larmor (Dr. Lodge characterised this as being perhaps the most suggestive communication made during the meeting, and expressed the hope that it would be further developed and printed); "A Special Class of Generating Functions in the Theory of Numbers," by Major MacMahon; "On Agreeable Numbers," by Lieut.-Col. Cunningham.

On Monday Mr. Horace Darwin exhibited and described the instruments used by the Committee on Earth Tremors. Prof. Milne presented the report of the Committee on the volcanic and seismological phenomena of Japan, and gave a most interesting account of the work done by himself and other observers in Japan.

The greater part of the sitting was taken up by a discussion on the teaching of elementary physics. This was introduced by Prof. Carey Foster, who exhibited and described some simple and cheap apparatus for teaching practical physics. The apparatus shown was well adapted for elementary class-work in heat and electricity. Mr. W. B. Croft followed with a paper in which he described the plan of science teaching at Winchester School, where, by an order of the Privy Council, science is compulsory for almost all the boys. The aim is to arrange for that which may be imposed on all as part of a good education—to supplement thought with the observing faculty. The scheme is also suited for those who may hope to become mathematical physicists and who should in boyhood devote themselves mainly to mathematics. For some boys science forms the best foundation of early education. Public schools are not generally adapted for these cases; but they can well be provided for by a liberal elasticity of system. Prof. O. Lodge read a paper in which Mr. A. E. Hawkins gave the results of his experience of science teaching in public schools, especially in Bedford School. He deprecated the influence of examinations on the teacher's work. Dr. Gladstone considered that apparatus should be not only cheap but simple. To use complicated apparatus was almost as dangerous as to depend upon blackboard work. He agreed with Mr. Buckmaster that too much work was usually expected from a science master. Mr. D. E. Jones emphasised the last point, and stated that instances had come under his notice where science masters had no time to prepare their experiments for class. The idea that science, unlike other subjects, ought to pay for itself, was much to be deprecated; it should not be neglected or abandoned in a school merely because it was costly. The teaching of physics as an educational instrument had not been sufficiently developed; and Continental schools were not much in advance of English ones in this matter. Mr. Jones gave an account of the system of teaching experimental physics as now carried out under Mr. Rintoul at Clifton School. Referring to the subsidising of science teaching in secondary schools, he pointed out that supervision of some kind must accompany public aid. If the evil effects of examinations were to be avoided, an efficient system of public inspection must be developed, and the inspectors should be men with experience of teaching work. Prof. Fitzgerald agreed with this; and Dr. Lodge expressed his regret that head-masters of schools could not be compelled to attend and listen to discussions such as this. The President, in concluding the discussion, said that an effort should be made to replace examinations by an intelligent system of inspection.

The last sitting was held on Tuesday the 19th. The President, as Secretary, submitted the report of the Electrical Standards Committee. This report defines the unit ohm as being the resistance of a column of mercury 106·3 cm. long, and of 14·4521 grammes mass at 0° C. The B. A. unit is equal to 0·9866 of the ohm thus defined. The French authorities had forwarded through M. Mascart four names which were proposed for the ohm of the 106·3 cm., and of these names the committee on the whole preferred "international." The resolutions respecting the electrical units passed at the Edinburgh meeting have now been accepted in Germany, France, Austria, Italy, and the United States, and throughout the British empire. Prof. Carey Foster said it should be known that the work of the Committee was really the work of the President (Mr. Glazebrook).

On Standards of Low Electrical Resistance.—Principal J. Viriamu Jones described the method of determining the ohm devised by Lorenz and used by Lord Rayleigh and subsequently by himself. The method consists in rapidly rotating a copper disc coaxially in the mean plane of a standard coil, the same current being led through the coil and through the low resistance which is to be measured. By varying the speed of rotation the difference of potential between the centre and the circumference of the disc can be made to counterbalance the difference of potential at the ends of the resistance. Prof. Jones pointed out that it is not only the most accurate method of measuring the ohm, but that it is especially suited for the measurement and production of very low resistances. Errors are necessarily produced in stepping down from a standard ohm, say by the potentiometer method, to a resistance of 1/1000 or 1/10,000 of an ohm. The Lorenz method is sufficiently simple and accurate to be adapted for the direct production of low resistances from a rotating disc and standard coil without going through the circuitous process of stepping up to a standard ohm and down again. The difficulty of making a good contact with the edge of the disc is avoided by using a tube with mercury running through it at constant pressure. Difficulties were encountered in using the electrically driven tuning-fork; for although it vibrated uniformly when once started, it was liable to a small change when stopped and started again. A series of experiments on a resistance of 1/2000 of an ohm was given in which the variation from the mean of the extreme values was only 1 in 12,000. Lord Rayleigh expressed his pleasure at the extraordinary accuracy now obtained by the method. In his own experiments the electrically driven tuning fork, instead of being stopped and started again, was kept on all day, and compared at the beginning with a free fork of the same frequency (128). In a recent paper Dorn has criticised the various methods used in the determination of the ohm, and has raised against Lorenz's method the objection that particles of iron in the disc might affect the result by altering the permeability inside the coil. This assumes that the presence of such particles would introduce a direct factor into the result, which would only be true if the whole space inside the coil were so filled.

Apparatus for Comparing nearly Equal Resistances.—Mr. F. H. Nalder exhibited a modified Wheatstone Bridge for comparing nearly equal resistances. In applying the Carey Foster method only a small portion of the usual metre bridge is brought into actual use, and in Mr. Nalder's modification only the part thus used (about 1 decim. long) is provided. This can be replaced by other wires of the same length but of different diameters and therefore resistances; of course the resistance per unit length in each of these is known. The comparison coils are wound in a single bobbin, so as to avoid temperature errors; these, and errors due to the thermo-electric effects, are materially reduced by the compactness of the whole apparatus. Dr. O. Lodge described a new form of galvanometer for physiological purposes. It was designed by himself and made by Messrs. Nalder Brothers. The nerve currents excited by stimuli are exceedingly feeble and, even with the so-called non-polarisable electrodes, the currents under investigation are frequently masked by other effects. Physiologists require an exceedingly sensitive ballistic galvanometer; but they appear generally to use needles which are far too heavy, and galvanometers which are too highly damped, and which manifestly cannot be so delicate as undamped galvanometers. The best form of galvanometer for their requirements is one which contains a very light needle built up of short pieces of highly magnetised steel wire and in which the coils are small and are wound up as close as possible to the needles. The instrument exhibited had four such coils and four needles, forming an astatic system suspended by a quartz fibre in a very weak field. Compared with the usual galvanometers of the same resistance its sensitiveness was at least twice as great. Prof. Boys has shown that excellent definition can be obtained from a small scrap of reflecting mirror; and Lord Rayleigh has shown that a pointer read by a microscope admits of just the same degree of delicacy as the mirror method. As biologists are accustomed to looking through microscopes, Dr. Lodge suggested that they might prefer to observe through a micrometer eyepiece a needle with a bee-sting as pointer. Prof. Fitzgerald suggested that the damping might be further reduced by hanging up the needle in a vacuous tube; and that the polarisations might be swept out by introducing capacities as in cable work.

A Simple Interference Experiment.—There is a well-known interference arrangement in which the object-glass of a telescope is covered by an opaque diaphragm containing two narrow slits. An observer looking through the telescope at a radiant point or slit parallel to the two narrow slits sees a bright central band of white light bordered by interference-bands. Lord Rayleigh had investigated the part played by the telescope in this arrangement, and found that the interference-bands can be equally well obtained by using a plain brass or cardboard tube, having at one end a single slit and at the other a double slit consisting of two fine scratches on a piece of chemically silvered glass about 1/100th of an inch apart. The President thanked Lord Rayleigh for introducing such a simple form of interference experiment, and said it should be more generally recognised that, inasmuch as the eye contains a lens and screen, we can frequently do without an observing telescope in optical experiments.

On Specula for Reflecting Telescopes.—Dr. A. Shafarik communicated the results of investigations which he has carried on since 1870 with the object of producing specula having greater tenacity than that of the Ross telescope. Silvered-glass mirrors produced by the Foucault method suffer rapid deterioration in the air of large towns. The addition of phosphorus is found to make bronzes harder and closer; and the addition of iron, nickel, or cobalt gives them a surprising degree of tenacity. In general the strongest alloys are those which contain the metals in atomistic proportions; and even a small deviation from this proportion appears to diminish the strength considerably. The process of grinding specula differs from that of grinding glass, for alloys are never homogeneous, they are full of crystals, as can be shown by partially dissolving out with acids. The relative tenacity of the Rosse speculum and of two other alloys is given below:—

R $= Cu_4Sn_1$	Strength	$= 1{\cdot}00$
ZN $= Cu_5Sn_1Ni$	,,	$= 6{\cdot}33$
D $= Cu_4Sn_1 + 4$ per cent Zn.	,,	$= 0{\cdot}52$

Several members pointed out that what was really required was a knowledge of the values of Young's modulus for the various alloys investigated, and that it was doubtful whether this was what the author referred to as "strength," or in what way the measurements had been carried out.

Prof. O. Lodge communicated a supplementary note on the ether. He had been asked how could dust polarise light if there was no mechanical connection between ether and matter? But on the electro-magnetic theory there was no difficulty, for light is not an ethereal oscillation but an electrical oscillation, and if the dust has different values of μ and κ from the ether it may affect the wave. Mr. Trouton stated that dust particles act as reflecting resonators with free periods. The President had to confess that he did not fully understand the sense in which Prof. Lodge used the word "mechanical," but considered that a modified mechanical theory (*e.g.* that of the quasi-labile ether) could explain all optical phenomena save those of electro-optics.

A discussion on "The Publication of Scientific Papers" was introduced by the reading of Mr. A. B. Basset's paper. Mr. Basset thinks it highly improbable that scientific societies of position and standing would consent to sink their individuality in order that arrangements might be made for the publication of all important papers in a central organ. The only feasible scheme seems to be the publication of a digest of papers by the co-operation of the various scientific societies; and if thought desirable, papers published in foreign countries might also be included. The development of a well-known periodical is an easier matter than the starting of a new one; and as many authors already send abstracts of their papers to NATURE, it might be worth while considering whether an arrangement could not be made with the proprietors of NATURE by which a supplemental number could be issued (say quarterly) containing a digest of the most important papers published during that period. Mr. J. Swinburne characterised the present system of publishing physical papers as being about as bad as it could be. Papers should be printed and circulated beforehand so as to leave time at meetings for useful discussions. He thought the Physical Society was the most hopeful body to look to, and advised the sending of all physical papers to it. Prof. Fitzgerald agreed with Mr. Swinburne that the publication of titles or indexes alone was unsatisfactory; it was like giving a stone to a man who asked for bread. Abstracts were better, for they gave a little bread with the stone, and he advised the translation of Wiedemann's *Beiblätter* into English. The *Philosophical Magazine* was the personal property of Dr. Francis, and even in the interests of science it was unreasonable to try to evict a man from his own property. The discussion was continued by Prof. Rücker, Prof. Carey Foster, and Lord Rayleigh; and the President in summing up said that the general opinion appeared to be that the matter should be considered by a committee of the Royal Society, if possible in conjunction with the Physical Society.

A new form of air-pump by Prof. J. J. Thompson was exhibited, in which two objects had been aimed at:—(1) to use sulphuric acid instead of mercury; (2) to make the pump self-acting and automatic.

Mr. F. T. Trouton made a communication on a peculiar motion assumed by oil bubbles in ascending tubes containing caustic solutions. A long glass tube was exhibited containing a bubble (about 3 inches long) of sweet oil in a very dilute solution of caustic potash. On inverting the tube the bubble begins to rise, and waves develop on its surface like the knots on a bamboo. These are unstable, and presently resolve into spiral waves which are more stable, because they leave spaces along which the solution can stream past the bubble. If the tube is inclined instead of inverted the bubble crawls up with a slow, caterpillar-like motion.

Dr. R. H. Mill gave a most interesting account of the relation between the temperatures of sea water and air in the Clyde sea area, and illustrated his remarks by an excellent series of slides. After a somewhat unintelligible communication by Mr. E. Major "On the disturbance of a fluid consisting of hard particles by a moving body, with special reference to the ether," the meeting closed with a hearty vote of thanks to the President.

CHEMISTRY AT THE BRITISH ASSOCIATION.

AMONG the advantages of the sectional meetings of the British Association are the opportunites they afford for discussions on scientific matters of special interest, and for the exhibition of experiments and specimens to a wider audience than is often available at the meetings of any single scientific society. The meeting of Section B at Nottingham will be chiefly remembered on account of the success of these two features, and it is to them that attention will be specially devoted in the necessarily brief account which follows.

The papers read on the opening day, after the President's address, were chiefly connected with the chemistry of the metals.

Dr. Gladstone gave an account of some tools and ornaments of copper discovered by Dr. Flinders Petrie and Mr. Bliss in Egypt and Palestine. From the chemical examination of some of these it is concluded that their necessary hardness was imparted by the presence of cuprous oxide.

In a paper by H. Harris and T. Turner a furnace used by the natives of Bengal for smelting iron was described. It is a small shaft furnace, about three feet high, and is capable of producing iron of great purity, from magnetic ore and native charcoal, without the addition of flux.

The Report of the Committee for obtaining an International Standard for the Analysis of Iron and Steel was read by T. Turner. The work of the British Committee is complete as far as the first four standards are concerned. A report, subject to slight revision, has been issued by the American Committee. Their results agree very well with those obtained by the English Committee. Standard 5 is held over for later investigation, after the work of all the committees is complete.

G. J. Fowler read a paper on the preparation and properties of Nitride of Iron. His results confirm those obtained by Stahlschmidt, according to which nitride of iron has a definite composition corresponding to the formula Fe_2N. It dissolves in acid according to the following equation:

$$2Fe_2N + 5H_2SO_4 = 4FeSO_4 + (NH_4)_2SO_4 + H_2$$

By means of this reaction the author, in conjunction with Mr. P. J. Hartog, has attempted to determine the heat of formation of the nitride. Agreeing experiments show it to be formed with evolution of about three calories.

Specimens of Cyano-nitride of Titanium obtained from Ferro-manganese were described and exhibited by T. W. Hogg. This substance has been found present, disseminated in microscopic crystals, in every specimen of high percentage ferro-manganese examined by the author. It can be obtained by elutriation of the carbonaceous residue, left after solution of the alloy in dilute hydrochloric acid, cupric chloride, &c., and has been identified by qualitative analysis, and by comparison with cyano-nitride of titanium obtained from the blast furnace.

On Friday the communications dealt chiefly with the chemical action of light, and the chemistry of the halogens.

Prof. Hummel read the Report of the Committee for investigating the action of Light upon Dyed Colours. Reds were the colours chiefly examined; of these the eosins were found to be the most fugitive. The great bulk of the fast reds belong to the azo-colours. It was especially pointed out that certain reds obtained from natural dye-stuffs are more fugitive than many artificial colours.

After the reading of this report, the President called upon M. Meslans, chief assistant to M. Moissan, to demonstrate the Method of Isolation, and the Properties of Fluorine. The experiments, which were followed with great interest by a large audience, were eminently successful. The apparatus used was the same as that already described in NATURE. On passing a current rather exceeding twenty-five amperes through the solution of potassium fluoride in hydrofluoric acid cooled by the evaporation of methyl chloride to $-23°$, fluorine was disengaged at the positive pole, its presence becoming evident by the strong smell of ozone. The combustions of silicon, boron, phosphorus, iodine and carbon in the gas, were shown with great success.

M. Moissan's apparatus for determining the density of fluorine was shown. After the vote of thanks to M. Moissan and to M. Meslans, proposed by Sir Henry Roscoe, and seconded by Prof. Thorpe, had been carried by acclamation, a telegram, at the suggestion of Sir Henry Roscoe, was despatched by the President to M. Moissan, congratulating him on the success of the experiments. A reply was afterwards received from M. Moissan regretting his inability to be present at the meeting.

Specimens of M. Moissan's artificial diamonds, and of the Carbide of Uranium which coruscates brilliantly on shaking the bottle containing it, were shown to the section.

Dr. S. Rideal described the results of his experiments to determine the Iodine Value of Sunlight in the high Alps. The experiments were made at St. Moritz in the Engadine, at a height of about 7000 feet, the method being exactly in accordance with that recommended by the Manchester Air Analysis Committee. From comparison of the results with some obtained in Manchester at the same time of year (viz., January), it appears that as much sunshine falls upon St. Moritz in one day as upon Manchester in ten. It is this large amount of sunshine doubtless which renders St. Moritz so favourable a health resort. It appears from some experiments made in the Alps by Prof. Dixon by and Dr. Kohn that above a certain height the amount of sunlight as determined by the liberation of iodine does not increase.

The Report of the Committee on the Action of Light on the Hydracids of the Halogens in the presence of Oxygen was read by Dr. A. Richardson. The committee have been investigating the conditions necessary to start the decomposition of hydrochloric acid in presence of oxygen. Experiments show that the presence of metallic salts is of great influence in this respect; the action of metallic chlorides is being especially studied.

The Expansion of Chlorine and Bromine under the influence of Light was shown on the screen by Dr. Richardson. For the success of the experiment it is necessary that the surface tension between the liquid, used as indicator of the expansion, and the tube in which it moves, should not be great.

Some interesting experiments made to determine the Rate of Evaporation of bodies into Different Atmospheres were described by Dr. Phookan. From the results obtained with naphthalene, it appears that vapours behave quite differently to gases in the manner in which they affect the rate of evaporation of this substance into them.

At the Monday sitting, Prof. P. Frankland read a paper introducing a Discussion on the Present Position of Bacteriology, more especially in its relation to Chemical Science. Prof. Frankland said that the present science of bacteriology really dated from the discovery, some twelve years ago, of methods for obtaining pure cultures. Since then the changes which have taken place have been chiefly in the methods employed for the recognition of bacteria. Microscopical characteristics, even when they have been brought out by mordant staining, have been found to be insufficient for this purpose. This was illustrated by the case of the cholera spirillum, as much difference existing between the different specimens of this spirillum, as between it and totally different species. Morphological have consequently been obliged to give way to chemical and physiological tests. Chemical tests being as yet few in number are apt to be treacherous, but they are capable of considerable extension. The typhoid bacillus, *e.g.*, will give no reaction with indol, the characteristic of the cholera bacillus, nor will it ferment glucose, but it will coagulate milk. With regard to the chemical products of the action of organisms the following questions suggest themselves:—Does the same substance yield different products with different bacteria? Do the same bacteria give rise to the same products with different substances?

Experiments with pure cultures have shown that one and the same bacillus will give identical products with such chemically related bodies as glycerol, arabinose, mannitol, &c. It appears probable that fermentability is due to the power possessed by a set of substances of yielding the same intermediate body which will give identical end products in all cases. This may explain why only those sugars which contain three carbon atoms or a multiple of three in their molecule appear to be fermentable.

The production of all three varieties of lactic acid by fermentation of glucose by different organisms has been accomplished. The mechanism of their formation was discussed in the light of Emil Fischer's formulæ for the glucoses.

The problems of selective fermentation were next dealt with, the cause of which was to be sought for in the slight differences of solubility &c., shown by active substances, when in combination with optically active isomeric bodies. One isomer is not found always to be quite unfermentable; in some cases both isomers can be destroyed if time be allowed, one, however, always disappearing first.

Of great interest is what may be termed educational culture, by means of which new characteristics may be artificially impressed upon an organism. A species of bacillus, morphologically identical with anthrax, but totally incapable of producing spores, may be obtained by cultivation of true anthrax in broth containing certain salts, such as potassium dichromate, or nitrate. The new characteristics will even persist after passage through the bodies of animals. On the other hand, by various means the virulence of pathogenic organisms can be greatly increased, though it has not been found possible to produce pathogenic from non-pathogenic organisms. It becomes probable, therefore, that naturally occurring bacilli will acquire new characteristics according to alterations in their condition of growth. The occurrence of non-toxic associated with, and morphologically identical with certain toxic organisms, *e.g.* those of diphtheria, anthrax, cholera, and typhus, is suggestive in this connection.

It is possible that ærobic organisms may become so far modified as to be active in absence of air. Much study is wanted in this direction, which affords special opportunities for observing the conditions of evolution among simpler forms of life.

The application of bacteriology to hygienic matters was next dealt with, with special reference to the bacteriological examination of water.

Finally, the disinfecting action of light under different conditions was spoken of. The generation of hydrogen peroxide, from air and moisture, under the influence of light, discovered by Richardson, would seem to play an important part in this action of sunlight, and the problem partly resolves itself into the study of the conditions of formation of this substance. The effect of different salts in modifying the bactericidal effects of sunlight was touched on, and in conclusion the necessity was urged upon chemists of a knowledge of biology and botany, to enable them to carry on bacteriological work, for which the first necessity had now become profound knowledge of chemistry and chemical methods.

In the course of the discussion, which owing to the length and comprehensiveness of the paper was not prolonged, Prof. Burdon-Sanderson advocated the establishment of an institute for research where chemists, biologists, and pathologists could mutually assist one another. It was resolved that, with his permission, Prof. Frankland's paper should be published in full.

The following papers were read in connection with the subject of discussion, viz., "Remarks on the Chemistry of Bacteria," by R. Warington, F.R.S.; "Fermentation in connection with the Leather Industry," by J. T. Wood; and "Some Ferments derived from Diseased Pears," by Dr. G. Tate.

On the Tuesday morning, Prof. H. B. Dixon opened what proved to be a most interesting discussion on Explosions in Mines, with special reference to the Dust Theory.

Opinions on this subject may be grouped under three heads:—

(1) That although it is possible to stir up and ignite a cloud of dust, the flame dies out and is not explosive; *i.e.* that a mixture of coal-dust and air *per se* is not explosive. This is the view held by Mallard and Le Chatelier.

(2) That, although a mixture of coal-dust and air *per se* is not explosive, a very slight addition of fire-damp, insufficient to be recognised by the Davy lamp, will render the mixture explosive. This view is supported by the experiments of Abel.

(3) That a mixture of fine coal-dust and air is *per se* explosive, and that the explosion once started in such a mixture can be propagated as far as the mixture extends.

Prof. Dixon then gave a brief history of the subject, dealing chiefly with the characteristic features presented by certain great mine explosions, and the experiments and results of the committees in different countries who have studied the question. The explosion in the Seaham Colliery in 1880 was specially dealt with. By means of a diagram it was shown that the only portions of the mine untouched by the explosion were those which were damp, and therefore free from dust. It was impossible to explain the method of propagation of this explosion otherwise than by the dust theory. Mr. Hall's experiments in 1891, in which a cannon was fired at the bottom of an old shaft in which coal-dust was suspended, were described, and photographs of some of the explosions shown. In some cases explosions could be brought about by these means, in others not, suggesting that the explosion was largely dependent on the character of the coal-dust. In conclusion, the importance of carefully testing for low percentages of fire-damp was pointed out, and also the possible advisability of using the fuses containing ammonium nitrate, recommended by the French Commission, on account of their low temperature of detonation.

At the conclusion of Prof. Dixon's address, Prof. Clowes exhibited his portable safety lamp, with hydrogen attachment for delicate gas-testing, described in the Proceedings of the Royal Society, vol. lii.

Mr. Galloway followed with a vigorous defence of the coal-dust theory. The dusty mines are always the deep mines which, owing to their greater warmth, are dry. In no mine of a less depth than 600 feet has any great explosion occurred. In damp mines explosions are limited in their area, while in dry mines they may ramify sometimes for a mile or so. In his opinion the experiments which had given rise to the belief that stone dust could convey explosions should be repeated. It was to be noted in drawing conclusions from laboratory experiments, that the conditions obtaining in the mine were more favourable to the production of explosions, the temperature being higher and the air drier and denser. In conclusion he showed that the anticipated evils resulting from watering the mine do not occur.

Mr. Hall, in the course of his remarks, said the higher the quality of the coal, the greater was the liability to explosion. He hoped that it had been proved to the satisfaction of practical people that coal-dust and air alone were competent to produce explosion.

Prof. Thorpe said that in an explosion caused by flour-dust, which had reduced a mill to a heap of dislocated bricks, he had received an object lesson, which had quite converted him to the coal-dust theory. Experiment had shown him that coal-dusts varied greatly in their capacity of exploding; some will not explode under any conditions, while others he could at any time explode with certainty.

Mr. Stokes declared himself in favour of the second of the three opinions mentioned by Prof. Dixon. It should not be concluded that large amounts of gas could not rapidly accumulate in pits. In one mine, in which for four years no gas had been found, an evolution of gas took place which in twenty-five minutes was sufficient to fill the workings. The lamps being good, no explosion took place; had it done so, all the evidence would have been in favour of its origin being due to coal-dust. He looked for remedial measures in improved explosives and safety-lamps, rather than in watering, which he considered insufficient to more than moisten the surface of the dust, unless carried to an impracticable extent. Others having spoken, mainly in favour of the coal-dust theory, Prof. Dixon, in reply, said that he was glad that all mining engineers now seemed to recognise the dangerous character of coal-dust.

After the above discussion, Prof. Smithells showed by experiment that iodine vapour will glow on heating, supporting his contention that the luminosity of flame may be due to incandescent gas.

The papers on organic chemistry read at Nottingham were very few, viz.—"On the Red Colouration of Phenol," by Dr. C. A. Kohn; "On the Salts of a new Sulphurea Base," and "On Citrazinic Acid," by W. J. Sell and T. H. Easterfield; and "On Ethylbutane Tetracarboxylate and its Derivatives," by Bevan Lean. In the course of the latter investigation two isomeric modifications of di-benzyl adipic acid have been obtained. The Report of the Committee on Isomeric Naphthalene Derivatives was read. The work done has been chiefly in connection with the orientation of mixed nitro and halogen derivatives.

The following pieces of apparatus were described, viz.—An Apparatus for Extraction for Analysis of Gases dissolved in water, by Edgar B. Truman, and a new form of Bunsen and Roscoe's Pendulum Actinometer, by Dr. Richardson and J. Quick.

GEOLOGY AT THE BRITISH ASSOCIATION.

OUT of the sixty papers contributed to this year's meeting of Section C. a considerable number, as might have been expected from the personal influence of the President, Mr. Teall, were on subjects connected with Petrology. Amongst this series, two of the most important were read by the eminent foreigners Prof. Brögger and Prof. Iddings, who had come over especially to attend this meeting. Next in number were the papers on Glacial Geology. The other papers group themselves into those on Local and Triassic Geology, Palæontology, Foreign Geology, and Vulcanology.

"On the Genetic Relations of the Basic Eruptive Rocks of Gran (Christiana region)" by Prof. W. C. Brögger.—This paper dealt with a series of eruptive bosses and laccolites forming a line of hills, of which the chief, in order from north to south, are (1) Brandberget, (2) Sölvsberget, (3) Dignæs. The main rock type in these bosses was called by the author Olivine-gabbro-diabase. It is basic (43 per cent. SiO_2) in 1, rather less basic (47 per cent.) in 2, and somewhat acid (49 per cent.) in 3; the more basic rocks were erupted first, then the less and less basic in order from north to south. From the intimate connection of the minerals in the different types, and the occurrence of all intermediate varieties, it was proved that these rocks had segregated in succession from a magma whose average composition was not unlike tha of the rock of Sölvsberget. The gradation in chemical composition produced a similar gradation in the mineral percentages, the felspar increasing from 12–64 per cent., and the pyroxene diminishing from 67–10 per cent. in a southerly direction. The author briefly stated that the contact metamorphism due to these plutonic rocks was quite different in character from that produced by a neighbouring mass of quartz-syenite on the same group of sedimentary rocks.

The eruptive bosses are accompanied by a great series of dykes and sheets of lamprophyric character, and varying from Camptonite to Bostonite. The author brought forward a quantity of evidence to prove that (1) these two extreme types, with silica percentages ranging from 40–56, had been derived from the same magma; (2) that 9 parts of Camptonite and 2 of Bostonite (about the proportion observed in the field) would give a magma of the composition of the Olivine-gabbro-diabase of Sölvsberget; (3) that these lamprophyric dykes had been derived from the same magma as the plutonic rocks; and (4) that the differentiation had been effected while the magma still remained fluid. It was further shown that the differentiation was probably due to the migration of less soluble constituents to the cooling margin, that the Camptonites had a composition closely allied to that of the brown hornblende of the area, and that while the essential cooling of the plutonic rocks had taken place in the eruptive bosses themselves, the dyke rocks had segregated before extrusion.

A subsidiary differentiation has taken place in some of the plutonic rocks, giving rise in the more basic Brandberget to a pyroxenite (with 95 per cent. of pyroxene) and augite-diorite, and in the less basic Sölvsberget to pyroxenite and Labrador-porphyrite.

Other points of importance to be noted were: (1) That under different physical conditions not only various mineral aggregates, but rocks of varying chemical composition had resulted from the crystallisation of the same magma; (2) that similar products result in this case from the segregation of an Olivine-gabbro-diabase magma, as have elsewhere been derived from a magma that has produced nepheline-syenites; (3) that the direction of segregation according to laws of crystallisation throws considerable light in the order of volcanic eruptions from neighbouring centres.

"On the Dissected Volcano of Crandall Basin, Wyoming," by Prof. J. P. Iddings. This paper was divided into a strictly petrological portion, and one dealing more broadly with the features of the area, and illustrated by slides brought over for the purpose by Prof. Iddings. The palæozoic and mesozoic deposits, almost unbroken up to the Laramic, had been disturbed and eroded before the outbreak of this volcano, now represented by lavas and breccias, penetrated by radiating dykes, and a core of crystalline rock, which is surrounded by a chaotic mass of scoriaceous breccia and massive flows. Erosion has removed at least 10,000 feet from the summit of the volcano, and has cut 4000 feet deeper into the valleys on either side of the centre. The lower breccia contains several varieties of andesite, the upper is chiefly basaltic, which is also the character of the chief massive flows. The dyke rocks are on the whole more crystalline, and contain biotite to the almost total exclusion of the olivine of the lavas and breccias. The core is chiefly of gabbro, which, however, passes into diorite, and even to aplite; these highly acid rocks appear to be amongst the latest of intrusions, but are cut by a few dykes of lamprophyric basic rock, which are also represented in the flows outside the core. The author's investigations show that under different circumstances totally different mineral aggregates arise from the cooling of the same magma. The basalts containing plagioclase, augite, olivine, magnetite, and sometimes hypersthene, the gabbros, plagioclase, augite, hypersthene, and biotite, besides some magnetite, orthoclase, and quartz, with or without hornblende. Further, the coarseness of crystallisation in the core and dykes seems to have been more influenced by the temperature of the surrounding rock than by the pressure to which they were subjected.

"On Structures in Eruptive Bosses which resemble those of ancient Gneisses," by Sir Archibald Geikie. He thought Lehmann's theory of the dynamical origin of foliation might explain granulitic gneisses with thin folia extending uniformly over a large area, but was inadequate to explain coarsely banded masses of irregular composition. These were better compared with the structures visible in the deeper parts of eruptive bosses in which minerals were segregated into bands, often parallel, and containing one prominent mineral in large crystals. Pegmatite veins, traversing not only massive unfoliated rocks, but the segregated bands, also occurred. These structures were best seen in ancient plutonic masses, but had also been lately observed by the author in the recent volcanic rocks of the Western Isles of Scotland.

On "Berthelot's Principle applied to Magmatic Concentration," by A. Harker. The paper deals with that type of concentration in which an igneous rock-magma, supposed originally homogeneous, has been differentiated by accumulation of the more basic ingredients in the cooler marginal part of the liquid. The author tries to find a physical cause for this action by comparing such a magma with a *saturated* saline solution, and applying Berthelot's "principle of maximum work" or the cognate one of "most rapid degradation." The migration of the least soluble ingredients to the part of the liquid most easily saturated would determine crystallisation, the process which in the case supposed would give the most rapid evolution of heat.

On "The Igneous Rocks of Barnavave, Carlingford," by Prof. W. J. Sollas. The white granophyre of this tract is intrusive into a black gabbro, in dykes of all sizes down to the most minute films and specks amongst the constituents of the latter rock. The result of this intimate intrusion is to convert the gabbro locally into a quartz gabbro, whilst the granophyre is loaded with fragments varying from large masses to crystal dust derived from the fracture of the gabbro, thus becoming a hornblendic granophyre. These intermediate rocks have been made out of a mixture of acid and basic constituents. The same author gave an analysis and microscopical description of an intrusion of Amphibolite at Glendalough, which, at its margin, had been transformed into Quartz-mica-diorite by the action of veins which were filled with potash felspar in the hornblende rock, but with quartz in the adjacent schists. Both these papers were well illustrated by lantern slides. Prof. Sollas also exhibited some pebbles from an ancient consolidated beach at Sandymount, co. Dublin, which had impressed one another on account of the perpetual jarring of the tram-cars running over them. He thought it was likely that earth tremors had had considerable influence in producing the similar pittings in Triassic pebbles. Bearing on this subject Dr. V. Ball showed incised bones and antlers from Irish peat-bogs, the cuts on which were due to pressure and tremors passing through the bog.

There were two papers, by Mr. W. W. Watts, on Irish petrology; one, "On a Hornblende-Pikrite intrusive in Cambrian Rocks at Greystones, co. Wicklow," described a rock consisting mainly of green and colourless hornblende enclosing grains of olivine, now converted into a mineral-like colourless amphibole; and another, "On the Perlitic Quartz Grains in Rhyolite of Sandy Braes Quarry in Antrim," in which the porphyritic quartz grains exhibited a series of concentric cracks, perlitic in character, the bulk of which were confined to the quartz crystals, but some of which traversed quartz and matrix alike.

"On Augen-Structure in Relation to the Origin of Eruptive Rocks and Gneiss," by Mr. J. G. Goodchild. Passing over that type of this structure more properly named phacoidal, the author confined himself to those "eyes" of minerals which have grown *in situ* in the rock where they occur. In cases where the original rock contained the necessary material for the formation of the "eyes," a rise in temperature or relief in pressure sufficient to enable the less refractory minerals to aggregate, but not sufficient to alter the chemical and physical state of the matrix, appears to have been all that is necessary. In other cases the author suggested that the necessary alkalies for the formation of such substances as secondary felspars may have been derived from the inner zones of the earth's crust.

A very useful and well-illustrated paper was read by Mr. Arnold-Bemrose, "On the Derbyshire Toadstone." There are two, at least, and may even be three or four, beds of olivine dolerite associated with tuffs. The rock is columnar and spheroidal, and may frequently be met with in an undecomposed state when the augite occurs in grains or ophitic plates containing felspar or olivine. There appears to be no foundation for the supposition that the toadstone contains no lead ore. All these rocks are surface lava flows.

Messrs. Howard and Small divide the igneous rocks of South Pembrokeshire into a northern group of rhyolites associated with quartz diorites and granites, often gneissose in character, and with epidiorites and hornblende schists, and a southern group at Musclewick Bay, consisting of porphyrites and dolerites in connection with a rock like a soda felsite. The authors are unable to fix the age of the rocks, but think the evidence goes to show that the rocks are, at the earliest, of Post-Silurian date.

Amongst the local papers, one by Prof. Clowes was of considerable interest. In it he showed the rock of which Bramcote and Stapleford hills and the Himlack stone were composed, was cemented by barium sulphate present occasionally in such quantity as to make 50 per cent. of the whole rock. Sometimes the crystalline cement was evenly distributed in minute crystals, but at others it was aggregated into patches which made the rock weather unevenly, so as to produce the so-called "pebble sand-beds." The author had no evidence of the form in which the cement was originally deposited—whether as carbonate or directly as sulphate.

Prof. E. Hull pointed out that the Nottingham water supply was derived from the Bunter sandstone, which was underlaid by the impervious Permian marls. Allowing that 20 out of 30 inches percolated into the sandstone, he calculated that the area of its outcrop from Worksop to Nottingham (120 square miles) must receive 40,000,000 gallons, all of which tends to flow eastwards. From the three stations about $5\frac{1}{4}$ million gallons were pumped daily. In a note on "The Borings at Netherseal Colliery," Prof. Hull determines the lowest rocks reached under Trias and Coal Measures at a depth of about 770 feet from the surface, as grits, sandstones, and quartzite, and attributes to them a Lower Cambrian age.

A number of more or less local papers relating to the new red sandstones were grouped together. Prof. Lapworth gave a general account of the subdivisions, distribution, and thickness of these rocks in the Midlands. Mr. Irving followed with a *résumé* of his researches for twenty years into the younger red rocks, referring to the classing of the Devonshire igneous and lower stratified red rocks as Permian in the recently published index maps of the Geological Survey. Mr. Metcalfe gave a note on the Gypsum deposits of Notts and Derbyshire. Baron von Reinach and Mr. Ussher recorded the discovery of Upper Magnesian limestone shells at Bulwell, and Messrs. Kendall and Gray showed that the presence of Permian marls at Stockport destroys the supposed evidence of unconformity there between the Permian and Trias.

After a brief discussion on Geological Education, Tuesday was devoted to glacial papers and discussion. Mr. Dugald Bell read an abstract of a most careful and important investigation into the shell-bearing clays of Clava in Nairn. The section in descending order, proved by excavation and boring, is as follows:—

	Feet.
(1) Surface soil and sandy boulder clay	43
(2) Fine sand	20
(3) Shelly blue clay with stones in lower part ...	16
(4) Coarse gravel and sand...	15
(5) Brown clay and stones	$21\frac{1}{2}$
(6) Solid rock, Old Red grit	

The highest part of the shelly clay is $503\frac{1}{2}$ feet above sea level, and the deposit appears to be continuous for a distance of 190 yards. It contains far-travelled, well-rounded stones (one must have come at least twelve miles) associated in different proportions from those in the overlying boulder clay or underlying gravel. The shells are mainly littoral, though some may have lived at depths not greater than twenty fathoms; although not intensely arctic, they indicate a colder climate than the present. The shells are well preserved, neither rubbed nor striated, and the deposit is a true marine silt, which if not *in situ* must have been transported in mass. The direction of ice flow being from south, or a little west of south, shows that the ice did not pass over any existing sea-bed before reaching Clava, and if the clay was carried from Loch Ness a submergence is postulated by the marine fauna there. The majority of the committee consider the evidence sufficently strong to prove a submergence to the extent of 500 feet, and they think the passage of ice to form the upper boulder clay would be sufficient to cause the cracking of the shelly clay and the crushing of certain of the shells. Detailed reports and lists of organisms are given, and a "minority report" on the evidence bearing against the view put forward above. Mr. Bell, in a paper, commented on shelly clay and gravel extending along the east coast of Aberdeenshire from the sea level up to about 300 feet, and endeavoured to explain it by the formation of lakes owing to the blocking of transverse valleys by the passage of ice across their mouths. In another paper the same author connected the granite boulders found in the Clyde Valley about Glasgow and Gourock with the mass of plutonic rocks occurring between the heads of Lochs Fyne and Lomond, and supposes them to have been brought by ice coming through Loch Fyne and Holy Loch, Loch Sloy, Loch Long, and the Gareloch, and in much smaller numbers by Loch Lomond.

Prince Kropotkin summed up his knowledge in the general glaciation of Asia. The Lowlands and Steppes, under 2000 feet in height, do not appear to have been glaciated; but all the mountain ridges rising over the steppes, the great border ridges like the Tian Shan, and the Alpine tracts fringing the plateau were covered with immense glaciers, which descended to within 1000 feet of the sea level. The Vitim Plateau, the N.W. Mongolia Plateau, the Pamirs, and the Great Khingim were extensively glaciated. The southern portion of the High Plateau, however, yields only indirect and not conclusive evidence of glaciation.

Prof. Sollas exhibited a large map, and gave an account of the Esker Systems of Ireland. Eskers have always been difficult to explain, and the best explanations have called in deposit by rivers; the difficulty has been to account for the disappearance of their banks. Prof. Sollas suggests that the sustaining walls may have been of ice, and that eskers are practically "casts of a glacial tunnel in gravel and sand." The eskers of Ireland are like rivers in their windings, and in the reception of tributaries at an acute angle. Deducing from the eskers the ancient drainage system of the Irish glaciers we find a smaller set draining from the glaciers of Sligo and Roscommon, and a much more important set, embracing the whole central plain, escaping by the valley of the Liffey

Mr. C. A. Lindvall, of Stockholm, reviewed the principal theories to account for the origin of the glacial period, and proposed to account for it by the partial submergence of Northern Europe to form an archipelago, through which escaped the cold ice-bearing currents from the Arctic Ocean. The author further endeavoured to show that the drifting of pack ice is sufficient to account for the striation, eskers, boulders, and other glacial signs in Scandinavia, Switzerland, and Scotland.

Prof. Bonney read a paper which gave rise to brisk discussion, in which Sir H. Howorth, Mr. Lamplough, Mr. Kendall, and others took part. He denied that there was any proof of considerable ground moraines in connection with existing glaciers, that glaciers were potent encavators, and that there was any evidence to show that ice had the power to scoop loose material from a sea-bed and pile it up from above the water-level; he suggested that boulder-clays like those of Britain, so different from Swiss moraines, may have had more than one origin.

Messrs. Abbott and Kendall have found shell middens with *Cardium edule*, a sheep's tooth, bird bones, and charcoal, at "The Quinta," on Penmaenmawr, and in the Aber Valley; they consider them due to human agency. Mr. Cameron described a mass of chalk, about a mile long, embedded in boulder clay at Catworth, in Huntingdonshire. Mr. De Rance concluded that the rock valleys of Lancashire and Cheshire were scooped by fluviatile agency when the land stood 300 feet higher than at present, and many of them are now choked with glacial detritus extending far into the Irish Sea. The so-called inter-glacial gravels do not occur on one horizon, and often several such beds are passed through in succession; they are regarded as having been partly formed in freshwater lakes and partly under the ice.

In the subject of palæontology three reports were presented. Prof. T. Rupert Jones described two species and two varieties of *Phyllopoda*, and made corrections, suggestions, and criticisms of other work; Mr. Laurie and Mr. Smith Woodward reported that progress was being made in working out the Eurypterids of the Pentlands, and in the registration of type specimens of fossils respectively. Dr. Traquair recorded *Cephalaspis* (*C. magnifica*) for the first time from the Orcadian area of the Old Red Sandstone; the cranial shield of this form, the largest known, is not less than 8½ inches in length. Mr. E. T. Newton gave a concise account of the Reptilia of the British Trias, including a notice of two entirely new forms, one related to *Stagonolepis*, the other a form intermediate between the crocodiles and dinosaurs. Mr. R. B. Newton recorded the first known shells from the English Keuper, discovered by Mr. Brodie and Mr. Richards in the marl of the Upper Keuper Sandstone of Shrewley, Warwickshire. They are referable to new species of the genera *Thracia*, *Goniomya*, and *Pholadomya*, and are associated with *Acrodus* and *Estheria*. Prof. Sollas gave a careful and illustrated description of the minute anatomy of *Monograptus priodon*, gathered from exceptionally perfect specimens; three layers are visible, the middle one being reticulated and thickening out to form the virgula and at the free edges of the thecæ. Mr. Montagu Browne referred several bones and teeth of *Termatosaurus albertii*, and of undetermined species of *Plesiosaurus*, to *P. rostratus* (Owen), from the Rhætic; he considered that the teeth of several species of *Saurichthys* would have to be divided between fish and labyrinthodonts; he also recorded the discovery of *Ceratodus* from the Rhætic.

In a clear and well illustrated paper by Mr. Walcot Gibson "On the Geology of Central East Africa" there is a description of the fringing reef bordering the land at Mombasa, succeeded by inland reefs rising up to 100 feet; the latter rests on a sedimentary series containing ammonites and ichthyosauria, and in turn resting unconformably on a great metamorphic series of gneisses, schists and intrusive granites, which occupy an area of fully two-thirds of Central East Africa. The remainder of the country is formed of recent volcanic rocks, forming great cones like Kilimanjaro, or arranged in lines running north and south. Most of the volcanoes are dormant or extinct, and none appear to be of great geological antiquity. Mr. R. D. Oldham exhibited geological maps of India on the scales of 96 and 32 miles to the inch, showing the recent work of the Geological Survey of that country; the smaller-scale map is to be published with the "Manual of the Geology of India." Mr. Myres showed that the fundamental rocks at Caria were crystalline, quartzose, and felspathic rocks with obscure foliation, traversed by dykes and necks of two ages, one pre-Cretaceous, which have supplied the volcanic rocks underlying the great mass of Cretaceous limestone, and the other from which the Tertiary volcanoes proceeded. The Cretaceous rocks were eroded before the deposit of the Tertiary shore beds, which pass away laterally into limestones; these beds are roughly correlated with those of Rhodes and Crete. Galena, pyrolusite, and a cobalt mineral are found in the ancient rocks.

Amongst the other papers it is only necessary to notice the following briefly:—Mr. Fowler described a fault at Cinder Hill, which causes greater displacement in the Carboniferous than in the overlying Permian rocks. Dr. Hicks pointed to the fragment in basal Cambrian rocks as indicating older series in Wales; Mr. Fox noted the wide extension of radiolarian chert in Cornwall; Mr. Bolton gave an account of the Skiddaw slates of the north of the Isle of Man, which had yielded rare trilobites and *Dictyonema*; Mr. Woodward's discovery of a bed of iron-ore on the horizon of the Cleveland iron between the middle and upper Lias of Raasay; Prof. Herdman's note on a consolidated shelly sand-bed from the bottom of the Irish Sea; Prof. Milne's illustrated account of volcanic and earthquake phenomena in Japan; Dr. Johnston Lavis's record of the condition of Vesuvius during the year, and his interesting note on the production of emerald-green augites by the action of enclosed particles of quartz and quartzite on a lava of Stromboli; Mr. Jeffs' list of geological photographs (140 in number) received during the year; Mr. De Rance's report on the circulation of underground water; and Mr. Kendall's report on erratic blocks, including the detailed survey of boulders in some considerable areas of the North of England.

In addition to the papers above reviewed, Section C took part in two discussions with other sections, and held one on its own ground. Mr. Topley, Prof. Bonney, Dr. Ball, Dr. Roberts, and Prof. Lapworth were the chief speakers on the limits of geology and geography; Prof. Sollas, Prof. Bonney, and Dr. Rothpletz, on the subject of coral reefs. The discussion on geological education was led by Prof. Cole, in a lucid paper on "Geology in Secondary Education," in which he advocated that, as a branch of history, geology should be taught to all secondary students. He advocated practical teaching so far as possible, and especially an acquaintance with the life history of the globe. Prof. Lebour, following, insisted on the careful selection of subjects in professional education and on the importance of making every part of the teaching as practical as possible, and encouraged experiments and field work, which he thought might very well be aided from the County Council's Technical Education Grant. These ideas were enforced by a number of subsequent speakers.

A word must be given to the series of photographs exhibited by the Photographs Committee, of which, however, only a small selection could be shown, those exhibited by the Scottish Geological Survey, and the specimen slides and maps to illustrate papers and discussions, kindly lent by Prof. Sollas, Messrs. Teall, Topley, Johnston Lavis, Gregory, and many others. This exhibition, if it can be continued with increased facilities at subsequent meetings, promises to become one of the most important features of the section's meeting

EVOLUTION AND CLASSIFICATION.[1]

As we have gathered up the scattered masses of botanical knowledge, laboriously wrought out by many isolated workers, and attempted to fit them together into a consistent whole, which should outline the structure of the temple Botany, we have found that the workmen have not always followed the same architectural plan, and have often used different units of measurement. With the increasing specialisation so noticeable year by year there is a corresponding lack of coordination of work. To this lack of coordination, this want of unity of measurement, this misunderstanding of plan, we can no longer close our eyes, and I therefore feel free to invite your attention to the following somewhat summary discussion of the causes of the present unsatisfactory condition, in the hope that we may thereby be enabled to see how we may make some improvement.

All botanical knowledge finally culminates in some kind of classification. The facts of histology, morphology, and physiology are of great biological importance, but the greatest of all biological facts is that the world is peopled with living things. We may group and arrange in orderly sequence the histological facts of the science; we may do likewise with the facts which the morphologist has discovered; we may make a classification of all the known physiological facts; but beyond and above these lies the greatest grouping of all—the grouping in orderly sequence of the organisms themselves whose histology, morphology, and physiology we have studied.

It is now a full third of a century since a great light was first turned upon all biological problems by the formulation of the doctrine of evolution by the master-mind of Darwin. In its light many puzzles have been solved, and many facts hitherto inexplicable have been made plain. We now know what relationship means, and we have given a fuller meaning to the natural system of classification. From the new point of view a natural classification is not merely an orderly arrangement of similar organisms. It is an expression of genetic relationship. Furthermore, in the light of evolution we now see the meaning of many reduced structures whose significance was formerly not at all—or but vaguely—understood. We have become familiar with the fact that degradation is a prominent factor in the vegetable kingdom. Evolution has by no means always involved an advance in structural complexity. Often this catagenesis is a result of parasitism or saprophytism, as is so well illustrated in the "fungi," where the degradation has gone so far that their relationship has to a great degree been obscured.

But there are also many cases of a catagenesis not due to a dependent habit in which we have evidence of a simplification from a more complex structure. Thus in the willows and poplars, where we have a raceme of very simple flowers, each consisting of a single ovary, or one to many stamens, it is readily seen that this simplicity is not primitive. The ovaries are not single carpels, but are composed of two or three united. The flower of the willow is simple by a degeneration from a higher type—probably a tricarpellary or pentacarpellary type—by the loss of its floral envelopes and stamens or pistils.

Every naturalist should be as familiar with these illustrations of evolution by simplification as he is with those of evolution by complication. In the growth of the great tree of life, while the development has been most largely in an upward direction, so that the great body of the tree has risen far above its point of beginning, there are yet multitudes of twigs and branchlets which droop downward.

I need not now, before a body of scientific men, speak of evolution as an hypothesis; for we know it as a great biological fact, about whose existence there is no shadow of doubt. A natural classification will conform strictly to the lines of evolution, it will be in fact a clear exposition of the successive steps in its progress. In such a classification the primitive forms will precede the derived ones, and the relation of the latter will be positively indicated. Moreover, in such a system there will be no confusion between the primitively simple forms and those which are so by derivation.

An examination of our common systems shows them sadly deficient in the essentials of a scientific classification. This is particularly true of the treatment of the flowering plants at the hands of English and American botanists. Nothing could show better the conservatism of botanists than the fact that for a third of a century after the general acceptance of the doctrine of evolution they are still using so crude an arrangement of the group of plants with which they are most familiar.

I may assume that it is well known to nearly all of us that the prevailing arrangement of the Dicotyledons does not represent the later views of any of the systematists. The fact is that the systematic disposition of the higher plants is at present a make-shift, maintained by conservatism, and a reverence for the time-honoured work of the fathers. It is unscientific to let our practice drag behind the present state of our knowledge: it is far more so for us to cling to the opinions of our fathers, through mere reverence, long after we know them to be untenable. It is not to the credit of our science that for a second time she has persistently held to a system through such considerations. For thirty or forty years after a natural system had been constructed by Jussieu, botanists as a body still adhere to the artificial system of Linne. Now, sixty years later, we find ourselves faced with a problem similar to that which Lindley, Torrey, Beck, and Gray met. History repeats itself with such exactness that, with the change of a word here and there, the arguments *pro* and *con* then used may be used to day. The system of Jussieu and DeCandolle is now as much a clog and a hindrance to the systematic botany of the higher plants as was that of Linne sixty years ago, and now as then it is the spirit of conservatism and of veneration for time-honoured usage which maintains the incubus.

Manifestly a system of classification which conforms to and is based upon the doctrine of evolution must begin with those forms which are primitive, or which as nearly as may be represent primitive forms. Since the flower is a shoot in which the phyllomes are modified for reproductive purposes, that flower in which the phyllomes are least modified must be regarded as primitive, while that in which there is most modification must be regarded as departing most widely from the primitive type. The simple pistil, developed from a single phyllome, is primitive and lower, the compound pistil is derived and higher. The several seeded compound ovary must be lower, and the compound ovary with but one seed must be higher. Separate stamens are primitive, united stamens, whether the union be with one another or with other structures, must be derived and consequently higher. So, too, when all parts of the flower are separate it is a primitive condition, and when they are united it is a derived structure.

Applying these principles to the flowering plants it becomes evident that in the Dicotyledons either the Apetalæ or the Polypetalæ must furnish our starting point. The Gamopetalæ are universally admitted to be higher than the groups just mentioned, and certainly do not contain the sought for primitive types. Even a hasty examination of the thirty-six apetalous families shows that they are, at least to a very large extent, derived from the Polypetalæ by the abortion of some parts and the entire omission of others. It will not be difficult to determine that the Ranales must take rank below all other Polypetalæ, in the sense of representing more nearly than any other group the primitive Dicotyledons.

The attempt to make a natural system by linking family to family in a long undulating chain, by concatenation, is unscientific because it absolutely fails to conform to the law of evolution. We must abandon the old classification and attempt one which in the light of evolution is rational. Let us not cling to the old because it is inconvenient to change, let us not cling to it through a mistaken reverence for the practice of the fathers, let us not cling to it as long as a flaw may be found in a new system. Science is ever abandoning the old when the old is no longer the true; it tears down the work of years when that work no longer represents the truth; and it dares to reach

[1] Abstract of Annual Address before Section G (Botany) of the American Association for the Advancement of Science. By C. E. Bessey, President of the Section.

out and frame a rational system even though some parts of it for a time rest upon hypothetical grounds.

SCIENTIFIC SERIALS.

American Journal of Science, September. — Fireball of January 13, by H. A. Newton (see p. 524).—On a photometric method which is independent of colour, by Ogden N. Rood. This is not based, like most previous methods, upon the comparison of the luminosities of two adjacent surfaces, but upon the shock that is produced upon the retina by a change of intensity of light. If one-half of a rotating disc reflects less light than the other by 1–50th of the whole amount, with appropriate rates of rotation a faint flickering will be noticed. This flickering disappears if the two halves have the same degree of brightness, whatever may be their colours.—On the oscillations of lightning discharges and of the Aurora Borealis, by John Trowbridge. Photographs were obtained of sparks having both great electromotive force and great quantity, produced by an alternating machine giving from 300 to 400 alternations per second, with the aid of a step-up transformer and an oil condenser. The oscillations were investigated by Feddersen's rotating mirror method. The sparks were about 2 cm. long, and the interval between two successive oscillations was one hundred-thousandth of a second. On each of the photographs reproduced some ten or twelve oscillations can be counted. The discharge is seen to follow exactly the same path three times in succession. After that it assumes the character of a brush discharge. By intercalating a non-inductive water resistance and a vacuum tube between the terminals of a suitable transformer it is possible to imitate exactly the phenomena observed when a vacuum tube is held in one hand while the other hand grasps the terminal of the transformer. In observing the striæ and waving columnar form of the light excited in this manner in tubes filled with rarefied gases, one is led to believe that the stratified form of the Aurora Borealis is produced in a similar manner.—On the estimation of chlorates and nitrates, and of nitrites and nitrates in one operation, by Charlotte F. Roberts. By means of the apparatus for the estimation of nitrates previously described, chlorates and nitrates together may be estimated. They are treated with manganous chloride, and the resulting gases are passed through potassium iodide and then into a Hempel's burette. The amount of nitric oxide, gives the amount of nitrate present, and the chlorate is estimated by deducting from the total chlorine liberated that due to the reduction of the nitrate.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, June 15.—Dr. Armstrong, President, in the chair.—The following papers were read:—Contributions to our knowledge of the aconite alkaloids. Part vi. Conversion of aconitine into isaconitine, by W. R. Dunstan and F.H. Carr. On heating the hydrobromide of the highly poisonous aconitine it is converted into the corresponding salt of its non-poisonous isomeride, isaconitine.—Part vii. Some modifications of aconitine aurichloride, by W. R. Dunstan and H. A. D. Jowett. Aconitine aurichloride may be obtained in three different physically isomeric modifications, melting at 135·5°, 152°, and 176° respectively.—Note on the stereoisomerism of nitrogen compounds, by S. U. Pickering.—A study of the properties of some strong solutions, by S. U. Pickering. The depressions of the freezing points of water, acetic acid, and benzene, by a number of organic non-electrolytes, indicate in all cases the formation of compounds of the solvent with the dissolved substance.—Studies on citrazinic acid, by W. J. Sell and T. W. Easterfield. The authors propose provisional formulæ for citrazinic acid and a number of allied compounds as the result of their work on the subject.—The essential oil of hops. Preliminary notice, by A. C. Chapman. A dextro-rotatory sesquiterpene $C_{15}H_{24}$, is obtained by the steam distillation of hops.—The sulphides and polysulphides of ammonium, by W. P. Bloxam. The author has obtained a number of crystalline double ammonium sulphides of the general formula $(NH_4)_2S, xNH_4\cdot SH$.—Sarcolactic acid obtained by fermentation of inactive lactic acid, by P. Frankland and J. MacGregor.—Hexanitroanilide, by A. G. Perkin.—The constituents of the Indian dye-stuff kamala, I., by A. G. Perkin. On extraction with ether, kamala yields rottlerin, $C_{11}H_{10}O_3$, isorottlerin, two resins $C_{12}H_{12}O_3$ and $C_{13}H_{12}O_4$ and a small proportion of a yellow colouring matter.—A quantitative method of separating iodine from chlorine and bromine, by D. S. Macnair. The method is based on the fact that, when treated with chromic acid mixture, silver iodide is converted into the iodate whilst silver chloride and bromide are converted into the sulphates.—Note on a form of burette for rapid titration, by L. Garbutt.—The use of sodium peroxide as an analytical agent, by J. Clark. By heating powdered minerals with sodium peroxide, the arsenic and sulphur may be rendered soluble.—Stibiotantalite, a new mineral, by G. A. By repeatedly heating fusel oil with fuming hydrochloric acid, pure laevo-rotatory amyl alcohol ($[\alpha]_D = -5·2°$) is obtained; by oxidising the alcohol, active valeric acid may then be prepared.—On the occasion of the Rothamstead jubilee, July 29 last, an address was presented to Sir J. Lawes and Dr. Gilbert by the President and Council of the Chemical Society.

PARIS.

Academy of Sciences, September 18.—M. de Lacaze-Duthiers in the chair.—On the teeth of hyperboloidal gearing, by M. H. Resal.—The shooting stars of the month of August, 1893, observed in Italy, by P. François Denza. Reports received from members of the Meteorological Association in all parts of Italy show that the August showers were observed under comparatively favourable conditions. The number of meteorites observed grew progessively from the first to the eleventh of the month, and the phenomenon exhibited on the latter date a greater brilliancy than usual. The maximum took place earlier than in previous years, and the greater density of the shower indicates a corresponding increase in the density of the meteorite swarm. The principal radiant was near η Persei, about R.A. 44°, Decl. + 55°. The steady annual displacement of the Perseid radiant and the unusual brilliancy of the swarm makes an interesting subject for future observation.—Circles or spheres "derived" from an envelope, plane or solid, of any class, by M. Paul Serret.—On the periodical maxima of spectra, by M. Aymonnet. It may be assumed that luminous waves comprising an exact number of molecular ranges are propagated with less friction than waves producing nodes in the molecules themselves. If, between two given limits, the incident radiation is sufficiently complex and intense, and the solid transmits all the maximum waves possible, these will, in the normal spectrum, differ in wave-length by twice the product of the index of refraction into the sum of the molecular diameter at absolute zero, its expansion at the given temperature, and its lengthening or shortening in the direction of propagation under the influence of the wave.—On the development of the pancreas in Ophidia, by M. G. Saint-Remy. The earliest stage observed in the snake, corresponding, as far as the pancreas is concerned, to the fifth day in the development of the chicken, shows distinctly the three markings, one dorsal and two ventral, observed in some other vertebrates. The ventral markings are completely isolated from the intestine, and detach themselves from the hepatic canal, forming two clusters of acini on the two sides. The dorsal marking, which is very voluminous, lies to the right of the duodenum, with which it communicates by a broad canal. It was this that was previously observed. The close connection between the hepatic canal and the pancreas is easily understood by observing the development of the latter from the three markings referred to.—On the coccidia of birds, by M. Alphonse Labbé. In the course of researches on parasites of the blood of birds, conducted at Roscoff, the presence of an intestinal coccidium, probably unknown hitherto, was verified in a large number of aquatic birds. It is a very small tetraspore coccidium with exogenous development. The pyriform capsule is not larger than 16 or 18 μ by 14 or 16 μ. An interesting characteristic is the frequent presence of two bright granules at the micropylar extremity. The presence or absence of polar granules in *Coccidium Roscoviense* appears to be determined by the culture in which the cysts were developed.—Vegetable anatomy of *Ataccia Cristata*, Kunth, by M. C. Queva.

THURSDAY, OCTOBER 5, 1893.

THE STUDY OF DIATOMS.

An Introduction to the Study of the Diatomaceæ. By Frederick Wm. Mills, F.R.M.S. With a Bibliography by Julien Deby, F.R.M.S. (London and Washington: Iliffe and Son, 1893.)

FEW forms in the organic world have been the subjects of such close, constant and varied study as the Diatoms. Their minuteness, their exquisite modes of growth, development and multiplication in the living state, and the beautiful refinement of symmetry and delicacy of surface chasing in their dead siliceous remains, have made them the special objects of interest, admiration, and often of serious study and research from certainly the dawn of this century until now. But there are few studies of living objects, at least of those that are extremely minute, that show more clearly that the real difficulties presented by them are understood only by those who thoroughly study them. It is the expert who knows how little is known concerning this most interesting if lowly group.

If no other purpose were served by this book, it would in a popular manner make this manifest.

There can be no serious doubt that much of the value that will attach to it as an "Introduction" is due to the very accessible and useful form in which Mr. Julien Deby's "Bibliography relating to Diatomology" has been presented to the student. The work consists of 240 pages; of these only forty-two are devoted to an exposition of the nature and habits of the Diatoms proper. There are three chapters relating to the collecting, the mounting, and the microscopical examination of these forms; but the forty-two pages are supposed to tell us all of importance that is known concerning these beautiful Algæ. Yet the Bibliography is enormous and includes the work and judgments of some of the leading naturalists of our century.

As this volume only aims at being an "introduction" to the study of these organisms, we have no right to anticipate exhaustive treatment in any branch of the subject; but we do not hesitate to affirm that the aim of its author would have been more efficiently reached had certain parts of his subject received a more liberal treatment.

No doubt the Bibliography opens to the amateur and the student almost every channel of knowledge, and will prevent him from attempting to repeat work already done, or from exhausting himself on work that it is at present more or less vain to attempt. But it would have been a great advantage to have seen in a concise form much that has been done in recent years.

Thus we find less than three pages devoted to the "Structure" of Diatoms; what is said is interesting and accurate; but, even remembering the aim of the author, we cannot consider it sufficient. It is quite true that no great generalisation of diatom structure has been arrived at; and we venture to think that much time and patient labour must be spent before it will be; nevertheless, during the last ten years some admirable glimpses at the wonderful architecture of these minute siliceous frustules have been obtained, showing that these silicified cases are not merely formed of two symmetrical valves united to one another by means of two embracing rings which constitute the connecting zone or girdle, and making together an elegantly carved box in which the species may be reproduced, but showing also that the most complete structural principles are embodied in their internal and external construction.

These are certainly not complete studies; but they do exactly what the zealous amateur wants: show the paths along which profitable study may be pursued.

This will apply with even greater force to the almost new branch of diatom work done in regard to "secondary structure" in the siliceous frustule. To those for whom this Introduction could be alone intended, few things could have a larger interest than this.

The nature of the extremely delicate "markings" of diatoms has been so zealously pursued by amateurs and microscopists generally, that it has brought upon them the frequently merited reproach of "Diatomaniacs." None the less it will be by the study of the perforations and physical constitution of the siliceous frustules that we shall ultimately obtain a true knowledge of their modes of motion, and even some aspects of their physiology. It would hardly have been supposed by those who wholly neglect, or even despise the study of the "markings" of diatoms that the wonderful "secondary structure" now demonstrated in many of these frustules had any existence. It may now, however, be taken for granted that every efficient manipulator possessed of a good microscope has demonstrated that, *e.g.*, *Coscinodiscus asteromphalus* is not only covered on its valves with the beautiful areolæ so long and so well known, but that these areolæ are in their turn delicately areolated. The coarse areolations so long familiar to us are for the most part approximately circular in outline; but inside these is a most delicately perforated membrane; and that this is related to the functions of the diatom there can be but little doubt.

Again it may be stated that these studies are incomplete; that is so; and, moreover, they require good instruments, and good manipulation of them, for satisfactory results; but we believe that it is such matters that the leisured amateur and the young student are most desirous of knowing in order to find suitable lines for profitable study.

It is true that the very remarkable work of Dr. Flögel on diatom sections, and some of his modes of operation are referred to, but these represent a far higher and more unusual class of research. The most elementary student should know something concerning them, and they are wisely referred to in this volume; but they do not compensate for the absence of efficient reference to the class of work we allude to.

The movement of diatoms receives careful treatment in this treatise; we believe, nevertheless, that more recent results might with profit have been referred to. The subject is in many senses one of the most difficult in the range of Biology. The three principal explanations, viz. endosmatic and exosmatic currents, the pre-

 A A

sence of cilia, and the existence of a pseudopodic extrusion of hyaline protoplasm, are carefully given. The author wisely inclines to the last. It is certain that one of the results of the use of apochromatic objectives during the last three or four years has been to enable us to demonstrate that not only are there perforations in the siliceous tests of the diatoms, but that in the raphé of some Naviculæ and kindred forms, there is a "great" perforation, which runs tube-like from the apices of the frustule to the central nodule; and this may be readily seen to lend itself to the pseudopodic extrusion and withdrawal of protoplasm; and we commend the study of the possibility of this to microscopists. Delicate stains may be used that will not immediately destroy the organism, and that will tend to make the "hyaline protoplasm" at least more manifest. But in this connection the work of Bütschli and Lauterborn cannot be neglected, Making *Pinnularia nobilis* the subject of research, they specially directed attention to its mode of motion. The motion in diatoms is of a peculiar kind, being frequently a series of jerks which carry forward the frustule in the direction of its length, and often carry it back along the same path. Yet the motion may be smooth and equable.

Bütschli conceived the idea of placing under the thin covering glass, laid upon the top of the water in which he was microscopically studying the *Pinnularia*, a minute drop of Indian ink. This in its ultimate particles is, of course, not soluble. Its extremely fine granulation was therefore of great value, for by means of the enormous multitude of these black granules he affirms that he was able to see an extremely fine thread, which was directed backwards. This, he contends, was a protoplasmic filament, but so fine, and, as we apprehend, so near in its refractive index to that of water, that it is otherwise invisible.

This filament, it is stated, is formed by jerks, and the diatom was simultaneously moved in the opposite direction; while at times the filament appears to be retracted.

That these results are of value, there can be no doubt, and they open a line of study that may be most profitable.

Mr. Mills has adopted the method of classification for the Diatomaceæ which for the present may fairly be considered the best; but we can but fervently hope that a series of detailed discoveries will at no very distant date make such generalisation possible as will superinduce a great simplification in this direction.

There is a very useful chapter on Mounting Diatoms, and some excellent teaching on the microscopic examination of these forms; and the whole is rendered complete by a chapter that will greatly aid the beginner, on "How to Photograph Diatoms."

We welcome this book; it will occupy a distinct place in the literature of the subject in our language at present, and will, we hope, make the way for a greatly enlarged and amplified second edition. There is much to praise in the volume, and what we have endeavoured to point out as deficiencies we do not treat as defects. The subject is so large that an author may well pause and wonder at what point an "Introduction" to such a subject should halt in details. But we think that what has been given will open the way for very much more, and hope that Mr. Mills may be called upon and induced to provide it.

We note some printer's errors in the book. It will suffice to call attention to page 6, where a period at the end of the second line destroys the sense; to the word "rhizopodo" for "rhizopodia" on page 13; to the wrong spelling of an author's name, as in the foot-note on page 5, and to a reference to "northern microscopic" for "northern microscopist" on page 159. D.

THE PROPAGATION OF ELECTRIC ENERGY.

Untersuchungen über die Ausbreitung der Electrischen Kraft. Von Dr. Heinrich Hertz. Pp. 295. (Leipzig: Johann Barth.)

A DISCOVERER'S own account of his work is always of interest, and when it is an epoch-making work and the account so clear and well described as to be intelligible to all, it deserves the most careful attention, and should be studied by all who feel any interest in the subject. Dr. Hertz's account of his discovery of the propagation of electric energy is eminently a work of this kind. The subject is of immense importance; the work described is of the highest order of experimental investigation; the results attained have contributed more than any other recent results to revolutionise the view taken by the majority of scientific workers as to the nature of electromagnetic actions. It is to be hoped that a translation of this account of one of the greatest advances in our knowledge of nature will soon be in the hands of all who care to learn how the functions of the ether have been raised from obscurity into light, from being in the opinion of many a pious belief to be the momentous question of the hour. Prof. Hertz gives in his introduction an interesting account of the steps by which Maxwell's theory may be connected with the older theories. These latter supposed action at a distance pure and simple, and postulated two fluids, &c., &c. They neglected the intervening medium. The second step was to introduce the medium as performing some function when it was a material medium, but still to retain the positive and negative electricities acting across the space from molecule to molecule. This was practically Mossotti's theory as to the properties of the dielectric founded on Poisson's theory of magnetic induction. M. Poincaré seems to have got to about this stage, or perhaps a little further. The third stage was to transfer the molecular action to the ether, but still to consider it as due to electrical fluids attracting and repelling one another, producing the etherial stresses. The fourth stage was to see that these attractions and repulsions of electrical fluids are quite superfluous, and to attribute the whole phenomenon to stresses in the ether set up by straining it. In this last stage there is no room for an electrical fluid with attracting and repelling properties and accordingly it is suppressed. What the structure of the ether may be which is strained, and thereby electromagnetic stresses produced, is still unknown, and consequently the nature of the strain is unknown. It certainly differs from the ordinary straining of a solid in two important respects. In the first place, the mechanical stresses are proportional to the squares of the quantities that represent the strains; and in the second place, they depend on the absolute strain, and not on the relative displacement of the parts of the medium. Solid structures can be invented that have laws of this kind. The change of longitudinal stress in a stretched string is proportional to the square of the transverse displacement, and, if the ends of the string are fixed, this stress depends on the absolute value of the displacement. Upon a foundation of a somewhat similar kind a theory as to the structure of the ether being like a solid in tension may be founded, which gets over many of the difficulties of the simple elastic solid theory of the ether. We are, however, still a good way off any really satisfactory theory as to the structure of the ether, but the leading idea of Maxwell's theory, that electromagnetic attractions and repulsions are due to some sort of strain in the ether, is the direction in which scientific men are at present seeking for a dynamical explanation of electromagnetism and for a structure of the ether. Prof. Hertz, however, seems content to look upon Maxwell's theory as the series of Maxwell's equations. This is hardly fair. Maxwell has done much more than produce a series of equations that represent electromagnetic actions. Weber and Clausius went very close to that without revolutionising our ideas as to the nature of these actions. Any exposition of Maxwell's theory which does not clearly put before the reader that energy is stored in the ether by stresses working on strains, is a very incomplete representation of Maxwell's theory. The bulk of Prof. Hertz's work is, however, not concerned with any theory, but with the practical study of electromagnetic propagation along conducting wires and throughout space. This is the work for which Prof. Hertz is so justly famous, and on account of which Hertzian oscillators, Hertzian receivers, Hertzian waves have become in the few years since 1888 the objects of universal attention. No physical experiments since those by which Joule founded the theory of the conservation of energy have produced as great an effect on science as these experiments here described by their author. The subject is brought down to last year, and the experiments of others are mentioned and discussed. In this connection it may be worth while remarking that the observation that the waves emitted by a Hertzian oscillator are of all sorts of wave-lengths was clearly stated by Prof. Hertz himself when he explained how rapidly they died out. For what is a rapidly dying out oscillation except a Fourier series of all sorts of waves? There is consequently no essential difference between these two statements. The first states more than the second, for it explains the character of what in the other statement is described by the vague term, "all sorts of waves."

The whole work is most interesting, and well deserves the best attention of all interested in the greatest scientific advance of the last quarter of the nineteenth century, a century that has seen thermodynamics founded by Carnot and Clausius, conservation of energy by Joule, bacteriology by Pasteur, the origin of species by Darwin, and the functions of the ether by Faraday, Maxwell, and Hertz.

OUR BOOK SHELF.

Helps to the Study of the Bible. By Henry Frowde. (London, 1893.)

THE publisher of this useful volume of *Helps* is to be congratulated on the production of a work which is far in advance of any other book of the same kind published in England. It consists of six parts, which comprise a brief history of the Bible and its most ancient versions, including terse remarks on its canon and authenticity; a summary of the contents of the books of the Old and New Testaments; an account of the Apocrypha, together with historical and chronological notices of the period; a series of chapters on the history, geography, geology, botany, zoology and ornithology of the country of Palestine, on the Jewish Calendar, weights, measures, money and time, and on the musical instruments of the Bible; and a concordance, atlas, list of obsolete English words, glossary of antiquities and customs, &c., referred to in the Bible. The book represents the collected learning of many eminent specialists and scholars, arranged in a handy form and most convenient for reference. The evidence relating to Bible history which may be derived from the recently established sciences of Assyriology and Egyptology, is illustrated by a series of beautiful plates, which cannot fail to be appreciated by every thoughtful reader of the Bible, and are worth more for purposes of explanation than many dissertations could ever have been. In the first plate the connection of the Hebrew alphabet with the hieratic writing of Egypt is shown, and from this we are led to the Latin and Greek alphabets and to the Rosetta and Moabite Stones. Facsimiles of the oldest Hebrew and Syriac MSS. of the Bible are next given, together with specimens of the text of the Vaticanus, Sinaiticus and Alexandrinus codices. The funeral customs of the Egyptians are explained by reproductions from bas-reliefs, papyri, &c., and from the monuments of Assyria and Babylonia a large number of important illustrations have been selected to throw light upon the various occasions upon which the Israelites came in contact with the "great king." The busts of the Roman emperors referred to in the New Testament, and the Temple of Diana, are the subjects of the plates inserted to illustrate the New Testament. At the foot of each plate is a brief description, which, we must hope, may in some cases be lengthened in future editions of this excellent book.

Differential Calculus for Beginners. By Joseph Edwards, M.A. (Macmillan and Co., 1893.)

MR. EDWARDS has put together in a handy form for schoolboys the elementary parts of his large treatise on the Differential Calculus. The subject is here presented in a clear and interesting manner for beginners, and it is to be hoped that the book will be useful in leading to a more general study of this indispensable subject than has hitherto been customary in this country.

The French schoolboy learns the elementary ideas as part of his Algebra, but with us it has been thought right that "calculus dodging" should precede the study of the calculus itself, under a mistaken application of the proverb—*Principiis enim cognitis, multo facilius extrema intelligetis.*

Geometrical applications are very judiciously introduced at an early stage, but considering that the first differential coefficient invented was for the expression of a Velocity, these applications would be rendered more instructive by the introduction of the notion of Time as the primary independent variable.

But "this is Dynamics" the schoolmaster will say, and so must be kept separate by a sort of water-tight bulkhead.

G.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Thieving of Assyrian Antiquities.

1. HAD I known that after having dissected my reply to the article entitled "Thieving of Assyrian Antiquities," which appeared in NATURE of the 10th ultimo, you had intended to add further objectionable remarks to it, I should have certainly declined to have had it published.

2. You seem, even now, to ignore the judgment of the High Court of Justice in the slander case of "Rassam *v.* Budge," and volunteer your own version of the story with which you have been supplied.

3. May I ask where you have found it reported about the evidence of the British Museum accountant and Sir Henry Rawlinson's deposition regarding the fragments of the national collection? If you have obtained your information from the latter's deposition that was certainly not revealed in the Press, and if it was supplied you by men who had no business to do so, then in fairness you ought to have quoted the other parts of the evidence. As for the "accountant," no paper reported what the Principal Librarian wanted him to say, and that was for a very good reason, because the Judge did not consider his evidence of any use, seeing that no one had disputed the purchase by the authorities of the British Museum, of Babylonian antiquities before I began my researches in Southern Mesopotamia, at the time when I was there and afterwards.

4. With regard to the cock-and-bull story about the bas-reliefs which are alleged to be at "Comford Hall," if you had said in your article, above referred to, that they *existed* in a private house in England, *instead of asserting that they were obtained by purchase*, I would have surprised you with further revelations that such "slabs" do exist in other houses in England and in different parts of Europe and America. Even half of the sculptures I had discovered in Assur-beni-pal's palace in 1853, belonging *legitimately* to the national collection, have been squandered, and part of them are now in the bottom of the Tigris.

5. As you seem to have allowed yourself to be imposed upon by malicious men who are not brave enough to put their names to the information with which they have supplied you, I must now close my correspondence, as it seems to me that your journal is not a proper channel through which justice can be obtained.

H. RASSAM.

6, Gloucester-walk, Kensington, W. September 23.

[THE above letter calls for some additional "remarks." We trust Mr. Rassam will find them less "objectionable" than the former ones.

1. The dissection to which reference is made consisted only of omissions of personal attacks, not even courteously worded, which moreover had nothing to do with the question of importance to the public.

2. Mr. Rassam is not happy here in his expressions. Nothing was stated in our article which was not openly stated in Court.

3. He is still less happy here. In his last letter he wished to make our readers believe that Sir H. Rawlinson's opinion on the "rubbish" Mr. Rassam had sent home was not stated in Court, and had been obtained by us in some improper way from the British Museum. In our "objectionable remarks" we charitably suggested that he had *forgotten* Sir H. Rawlinson's deposition containing this opinion was read in Court. It now seems that Mr. Rassam had not forgotten it in the least.

With regard to the accountant; the counsel for the defendant did say what the accountant was to prove, and the Editor does not see what the Principal Librarian had to do with it.

4. Why does Mr. Rassam take the trouble to misquote us by writing "Comford" instead of "Canford," and then to put his misquotation in inverted commas? The "story of a cock and bull," which we took from one edition of Murray's Guide is repeated in more detail in a later one, and even the name of the donor is mentioned, Sir A. H. Layard.

The more "revelations" Mr. Rassam can supply; the more he can show that property "belonging *legitimately* (the italics are Mr. Rassam's) to the national collection" has been squandered; the more reason there is for the inquiry to which we have pointed.

5. Requires no comment except that not a single inaccuracy on our part has been established.—ED. NATURE.]

Vectors and Quaternions.

I WISH to make some observations in reply to the letter of Prof. Knott which appeared in NATURE (June 15, p. 148). For my part I have nowhere condemned the system of Hamilton and Tait as "unnatural" and "weak"; on the contrary, I have always spoken of it with respect and admiration. To appreciate its value and high place in analysis it is not necessary to be blind to its imperfections and limitations. As to whether my work is mere innovation and a recasting of quaternion investigations, I leave to the judgment of those who read my papers. I wish merely to remark that Prof. Knott says nothing about exponentials, and that he has not pointed out what quaternion investigations are recast in my paper on "The Fundamental Theorems of Analysis Generalised for Space." It is the duty of a critic to state correctly and fully the principles which he criticises; this has not been done; my position has been misrepresented. It may aid the scientific discussion of this matter if I state briefly the principal positions I have taken, and the replies that have been given.

I have said that the quaternion notation can be improved. As regards notation, Hamilton himself was an innovator, and in his writings he apologises for the introduction of the strange symbols S, V, T, K, U, I, &c. My aim has been to generalise as much as possible the notation of ordinary analysis, as it is desirable to have one harmonious algebra, with easy transition from line algebra to plane algebra, and from plane algebra to space algebra. Prof. Tait himself has said in one of the prefaces to his treatise that a revolution in the matter of notation must ultimately come; but I infer from the ecstacy of his admiration, that Prof. Knott considers it part of the original brightness of the Archangel.

I have said that the quaternion definitions are not all that can be wished for; I have pointed out what appear to be defects, and I have attempted to remove them. According to Prof. Knott, "the quaternion originally defined as the quotient of two vectors, can also be represented as the product of two quadrantal versors." I reply that what is wanted is not an original or temporary definition of "quaternion," but one that will stand throughout; that in strains we have a quotient of two vectors which is not a quaternion, but a dyad; that we do not ask for a representation, but a definition; and that the representation indicated involves the idea of a versor, which, leaving out a mere multiplier, is the very thing to be defined. Further, the following questions may be asked: If by a quaternion is meant the quotient of two vectors, how can the product of two vectors be a quaternion? We have also the nice distinction that a quaternion may be represented by the product, but not by the quotient, of two quadrantal versors. It is certain that the product and the quotient of two quadrantal versors are quantities of the same kind; if the one is a quaternion, so is the other.

I have said that some of the fundamental principles of quaternions require to be corrected, especially the one which identifies versors with vectors. I have said that if α denote a unit-vector, then $\alpha^2 = 1$, not $= -1$. It is not a bare assertion that "to my mind" it appears so; a reason is given. Let a body of mass, m, have at any time a linear velocity whose rectangular components are a along the axis of i, b along j, and c along k; the kinetic energy of the body is $\frac{1}{2}m(ai + bj + ck)^2$, that is, $\frac{1}{2}m(a^2 + b^2 + c^2)$, not as quaternionists would have it, $-\frac{1}{2}m(a^2 + b^2 + c^2)$. The convention involved is one that pervades the whole of analysis, namely, that the product of two lines having the same direction is positive, while the product of two lines having opposite directions is negative. As kinetic energy is a square, the two lines must always have the same direction.

I have said that if $\alpha^{\frac{\pi}{2}}$ denote a quadrantal versor, then $\left(\alpha^{\frac{\pi}{2}}\right)^2 = \alpha^{\pi} = -1$, and that Hamilton's rules apply to versors, not to vectors. Prof. Knott says that I advocate a system which loses the associative principle and gains nothing but a positive sign and an undesirable complexity in transforming by permutations. Readers of NATURE will be surprised to learn that I advocate nothing of the sort. What I do advocate is to treat vectors as vectors, and versors as versors, and I show that the products of versors differ essentially from the products of vectors in that the associative rule applies to the former, but not to the latter. Prof. Knott justifies the treatment of quadrantal versors as vectors, because they are compounded according to the parallelogram law. It is true that the components of a quadrantal versor are so compounded, because every versor involves an axis; but the minus comes in, not on account of the axis, but on account of the angle of the versor, the very element which differentiates it from a vector.

I have said that $\nabla^2 = \frac{d^2}{dx^2}+\frac{d^2}{dy^2}+\frac{d^2}{dz^2}$ is more consistent with analysis than $\nabla^2 = -\left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}+\frac{d^2}{dz^2}\right)$, and I have remarked that in works on mathematical physics, even in Kelvin and Tait's "Natural Philosophy," the minus was dropped. A sign that can be so readily dropped has probably got no good reason for its appearance. In reply, Prof. Knott says that "when $\nabla^2 v$ occurs in ordinary non-quaternion analysis, it is used in the sense of the *tensor*, for only as such can it come in." This explanation does not explain; for "the name *tensor* is applied to the *positive* number which represents the length of a line" ("Hamilton's Elements," p. 164). Now the ordinary analysis is not limited to signless quantities, but embraces quantities which may be positive or negative. Why then is the minus dropped in an analysis where sign is essential? I asked for a proof of the principle that $\nabla(\nabla\omega) = \nabla^2\omega$; it is replied that "in quaternions there is no doubt whatever." Are we permitted, then, to doubt it as a truth in ordinary analysis, being true only in quaternions? If it is a matter of convention, no one desires two contradictory systems of analysis; if it is a matter of truth, it cannot be true "in quaternions" and not in ordinary analysis.

I have said that the rule $ij = k$ expresses what is true in space of three dimensions. Prof. Knott asks: "If a vector cannot be a versor in product combinations, what is the signification of the equation $ij = k$?" Let us first of all remove every ambiguity from the equation. We have then in all three cases: first, i and j both quadrantal versors; second, i a versor and j a vector; third, i and j both vectors. To distinguish between a quadrantal versor and a vector, let the former be denoted by $i^{\frac{\pi}{2}}$. Then $i^{\frac{\pi}{2}} j^{\frac{\pi}{2}} = -k^{\frac{\pi}{2}}$ means the forward order being taken, that a quadrant round i followed by a qudrant round j is equivalent to a quadrant round the opposite of k. Again, $i^{\frac{\pi}{2}} j = k$ means that the vector j, when turned through a quadrant round i coincides with k. Finally, ij means the unit of directed area which has i for base and j for altitude; for some purposes it may be represented by k on the principle that the axis of a plane may be specified by the axis which it wants; but at p. 92 of "The Principles of the Algebra of Physics," I have shown that the several types of products of vectors may be formed independently of that principle. Prof. Knott states that he fails to see what physical considerations have to do with mathematics of the fourth dimension. It is evident, however, that his perception cannot be taken as a criterion of truth, for every type of product of four vectors is geometrically real excepting the one which supposes them all independent of one another.

I have said that the rules for differentiation are much simplified when vectors and versors are not confounded. In proof of this I invite comparison.

I have said that the principles of quaternions can be greatly extended. In my papers will be found for the first time the extension of space analysis to logmarithmic spirals and to hyperbolic trigonometry. The connection of the latter with non-euclidean geometry is also pointed out. As further evidence of the fruitfulness of my notation and principles I may mention that I have just read before the Mathematical Congress assembled at Chicago two papers—one on "The Definitions of the Trigonometric Functions," the other on "The Principles of Elliptic and Hyperbolic Analysis." These papers give the trigonometry of the elliptic and hyperbolic surfaces.

As regards Prof. Knott's closing quotation from "Paradise Lost," I feel like the Senior Wrangler who, having read through the poem, remarked that it was all very pretty, but he didn't quite see what it proved. I close with a quotation which is from as good a book, and possesses more logical force: "Ye shall know them by their fruits. Do men gather grapes of thorns, or figs of thistles?" ALEXANDER MACFARLANE.

Chicago, Ill., August 26.

Astronomical Photography.

THE letter from Lord Rayleigh in your issue of August 24, on the subject of "Astronomical Photography," will, it is to be hoped, elicit some information from photographic experts.

Meanwhile, accepting what Lord Rayleigh says as to the present possibilities in the preparation of plates, I fail to see where any considerable saving is to be effected in the cost of the apparatus, as he appears to suggest.

For astronomical photography a pair of telescopes are required. The larger of these is employed to take the photographs, and the smaller acts as a guider. Supposing that plates could be obtained which were acted upon by visual rays, while comparatively insensible to the violet and ultra-violet light, this would simply mean that both the objectives would have to be made visually perfect, instead of having one of them as heretofore corrected for violet and ultra-violet light. A photographic objective is no more costly than a visual one of the same aperture; and as to mounting clockwork and dome, there could be no difference in expense.

Of course, if the necessity for a separate guiding telescope could be avoided by the adoption of Lord Rayleigh's suggestion, there would in general be some saving of expense; it should, however, be noted, that even when reflectors are employed for taking the photographs, it has not been always found desirable to dispense with the guiding telescope, though in this case, of course, the question as to the nature of the plates cannot arise at all.

In the particular instance of the instrument now proposed for Cambridge, the guiding telescope is already to hand in the shape of the present Northumberland instrument.

It is certainly easier to test the qualities of an objective corrected for visual rays than for photographic rays (if I may still use language which Lord Rayleigh has pointed out as incorrect). On this account it would, therefore, be desirable to have plates such as he refers to, rendered available for astronomers engaged in photographic work. ROBERT S. BALL.

Observatory, Cambridge, September 12.

P.S.—Sir Gabriel Stokes, after reading the above, writes: "I would ask whether in an orthochromatic plate the blue and violet are impressed more feebly than the rays which are visually the brightest. It may be so, but I do not happen to know whether it is."

The Constellations of the Far East.

WITH regard to the questions asked by "M. A. B." about the grouping of stars into constellations (NATURE, August 17), I venture to answer the last two, which the limited knowledge of an Oriental may partly meet, hoping thereby to interest some of your readers.

I do not consider that each race necessarily relies on its own plan in the fabrication of constellations. The Coreans and Anamese are said to be still adhering to the Chinese system, and till lately the Japanese were doing so. It is strange to find the latter, replete with so peculiar mythology, on which the national claim for high ancestry rests, possessing very few vernacular constellations.

Undoubtedly the Chinese system is of peculiar aspect. A name is given to a "Seat," which is sometimes a single star, but in general a group of stars, varying in number from two to twenty or thirty; and in one group, the Imperial Body-guards, they amount to forty-five. Occasionally the same stars are at once named collectively and individually; thus, the first seven stars of Ursa Major are grouped into Peh-tau or the North Ladle, of which the scoop consists of Shu α, Siuen β, Ki γ, and Kiuen δ, and the handle of Yuh-hang ϵ, Kai-yang ζ, and Yau-Kwang η. With Polaris as the centre, the heavens are radiantly divided into the twenty-eight "Inns" of unequal breadths, each division being denominated after its typical constellation, besides enclosing numerous Seats subordinate to the latter.

The fundamental idea of the plan is enigmatically expressed thus: "Sing (the star) is Tsing (the spirit)." Its solution continues: "Its body grows on the earth, and its spirit is perfected in the heavens." Consequently, various worldly facts and acts that have occupied the Chinese attention, not excepting some now quite forgotten, remind us of their past existence by means of the stellar and constellar names fashioned after them from fancied resemblances or analogies.

How closely this association of the heavenly and worldly phenomena was made, a few examples will suffice to show. The Bow-and-Arrow, though apparently separate, formed but one group, because an archer could perform well without an assistant; but, on account of the supposed impossibility of one's pounding, without an attendant to the mortar, the Mortar was distinct from the Pestle. Imitating the civil institutions of old times, Polaris, entitled the Emperor of Emperors, and his Empress, Imperial Heir, &c., constitute "Ché-wi Palace," with thirty-two subservient Seats, mostly named after officials. Besides, the four "Imperial Thrones" are established, one of which is surrounded with seventeen dependents, chiefly with the names of court-buildings in "Tai-wi Palace," while the other, amidst the "Celestial Emporium" has its seventeen subjects, named after provinces, market buildings, and measures.

For contriving the applications of the plan, the following methods seem to have been observed:

(1) Number, *e.g.* the Five Princes, Four Councillors.

(2) Magnitude, *e.g.* the Squire Captain, set apart from the Squires.

(3) Form, *e.g.* the Canopy, Celestial Coin, Ascending Serpent.

(4) Relation of positions, *e.g.* the Deep Water, Celestial Hook, and Celestial Pier, entirely and partly in, and along the Celestial River (the milky-way).

(5) Direction of the Compass, *e.g.* the South Gate, North Pole.

(6) Colour, *e.g.* Excrementum.

The objects and attributes resorted to for modelling the stars and constellations may be classified as follows:—

(1) Heavenly Bodies, *e.g.* the sun, moon, milky-way.

(2) Meteorological phenomena, *e.g.* thunder and lightning.

(3) Topographical Divisions, *e.g.* the field, tumuli, park, pond.

(4) Civil Divisions, *e.g.* Tsin (a province), Chang-sha (a shire).

(5) Animals, *e.g.* the dog, wolf, fowl, fish, snapping-turtle.

(6) Agricultural Products, *e.g.* bran, hay, gourd, cereals.

(7) Parts of Body, *e.g.* the tongue, penis.

(8) Human Actions, *e.g.* the cry, weep, slander, punishment.

(9) Family Relations, *e.g.* the son, grandson, adult, old man.

(10) Occupations, *e.g.* the farmer, weaving-woman.

(11) Buildings and Departments, *e.g.* the castle, granary, kitchen.

(12) Implements, Furniture, &c, *e.g.* the lock, drum, bell, bed, ship.

(13) Titles and Officials, *e.g.* the feudatory, ministers, generals.

(14) Heroes, *e.g.* Fu-yeh, Tsau-fu.

(15) Philosophical and Theological Notions, *e.g.* positiveness, virtue, prodigy, fates, fortune, wrong, &c.

As far as I could expound, the system implies certain peculiarities. First, it preserves some abstract notions, thus pointing the way towards investigations on the early Chinese speculations. Secondly, portions of the system severally harmonise with the conditions of the Chinese social system that existed for many centuries before the dawn of the Han dynasty (*circa* 200 B.C.), when it seems certain that the nomenclature was well-nigh finished. In the third place, I may mention that after careful revisions of the whole list containing more than three hundred names of the Seats, I have found but two that have had any reference to the sea, viz., "South Sea" and "East Sea," the rather vague notions of old usage indicating some uncivilised territories; and with this only exception there occur no names of marine beings such as Cetus, Delphinus, and Cancer. This fact probably justifies a historical theory that locates the cradle of Chinese civilisation on a land distant from the seas.

I do not know precisely what system is current among the Indians of the present day; but assuredly at least once they made use of their own plans, and mapped out the heavens into the twenty-eight divisions, each division with its typical constellations and their subordinates, as is often alluded to in the Buddhist writings of the North. The equality of number of the divisions in the Chinese and Indian systems is striking; but evidence favours the belief in their sporadic growths and analogous development. The Chinese records of the typical constellations date farther back than the epoch of their intercourse with the Indians; in fact, the Indian constellations, as is obvious from their mythic apotheoses and the articles of sacrifice, including such abomination to the Buddhist as blood and bird's-flesh, are essentially of Brahmanical type, and thus proclaim their priority in existence to the event of the Buddhist mission to China, which marks the era of the mutual acquaintance of the two nations.

When we see in the old Chinese works on Indian names, those of the Indian typical constellations, such as Rivata, Kamphilla, &c., not literally interpreted, but merely identified with those of the Chinese, such as Shi, Fang, &c., every two divisions of corresponding order seem to have had extents almost coinciding in the two systems.

Twan Chin-shi (*circa* 800 A.D.), a Chinese Pliny, in his "Miscellanies" has left us an extract from Indian records, registering the objects with which the Indians used to associate the forms of some typical constellations of their own. Of the Chinese typical constellations, the original resemblances or analogies can still be traced, through their names and characters, with the help of the descriptive remarks in cases of difficulty. Replying upon these authorities, I will now proceed to compare the cited objects of alleged resemblances or analogies, in order to see whether and how the fancies of the two nations converge into or diverge from one another, in the establishment of one most conspicuous, and thence typical constellation, out of the stars scattered over a division almost identical in the two systems.

Chinese names.	Remarks.	Objects of Indian fancy.
1. Niu (Taurus).	The bull with horns.	The head of a bull.
2. Wí (the Tail).		The tail of scorpion.
3. Liú (the Willow).	Curved, with a tip bent, like the willow (twig). In Chinese astrology, this is the patron of the snakes.	The serpent.
4. Wei (the Stomach).	The legs of a vessel for cooking.	Same.
5. Su (the Horn of Scops).		The head of deer (with antlers).
6. Kí (the Winnowing fan).		The horns of cattle.
7. Tsing (the Well).		A footprint.
8. Kwei (the unsettled).	Its character, combined with that for "foot," forms one for "kneeling," and its original hieroglyphic represents "one kneeling"; hence it is probably of analogous plan with Hercules (kneeling).	The dimple of woman.
9. Kwèi (the Ghost).	The coffin (with corpse).	The Saint's Breast.
10. Pih (the Handle-net).		A hat.
11. Sing (the Star).	The hook.	The river-bank.
12. Fang (the Screen).		Beads of head-dress.

It appears from the above comparisons that sometimes quite analogous or even identical plans might sporadically grow among distinct nations, probably due to the pronounced readiness to be grouped afforded by the stars of not very different brightness and relatively situated in a manner which at once suggests a definite outline.

In conclusion, I should be inclined to state that the peculiarity, in cases where it exists, can no doubt be of great value to students of sociology, as it may help to some extent towards the attainment of various important discoveries. For instance, a Chinese constellation, Nü, or the Woman, is described as very much simulating Ki, or the Winnowing Fan; and this might be closely connected with the frequent occurrence in Chinese works of a figurative phrase, "to serve the fan and broom" in the sense of "getting married." On the other hand, as to the merit of its use for ascertaining the race-affinity, my opinion must be somewhat negative, for, while instances are not wanting of such remarkable analogies among such heterogeneous nations as the Chinese and Indians, the subject is decidedly one of those social acquirements of highly transmissible nature, its present features being more the result of the national intercourse than that of the race-affinity.

KUMAGUSU MINAKATA.

15 Blithfield Street, Kensington, August 31.

Mr. Love's Treatise on Elasticity.

HAVING now returned to England, I have had an opportunity of examining my paper on wires (Proc. Lond. Math. Soc. vol. xxiii.), and I find that the discrepancy between my results and those given by Mr. Love, on p. 169 of his book, is due to a slip in my own work. On comparing my equations (11 and 15), it will be seen that in the latter equation the term $-\rho(\sigma p - \sigma r \cos\theta)^{-1}dw'/d\theta$ has been omitted. The value of w' is correctly given by equation 31, and when the omitted term is inserted in equation 32, the resulting value of g will be found to lead to values of the couples identical with those given by Mr. Love.

As I am strongly of opinion that the best way of constructing a satisfactory theory of shells and wires is to use the method of expansion, coupled with the hypothesis that all stresses which vanish at the surface may be treated (to a certain degree of approximation) as zero throughout the substance of the shell or wire, I am exceedingly glad to find that the apparent discrepancy is due to a small slip in my work, and not to any defect in the principles upon which the investigation is based. The question as to the values of the couples may now be considered to be completely settled.

A. B. BASSET.

September 28.

New Caledonian Pottery.

I AM extremely anxious to be informed on a little matter, and you are my only resource. In the *Journal of the Anthropological Institute*, August, 1893, vol. xxiii. page 90, Mr. J. J. Atkinson describes the making of New Caledonian pottery. The ingenious device of the pebble as a pivot is interesting. But Mr. Atkinson always says *he*. Do the men make pottery in New Caledonia, or is this a case of what the country school teacher termed the men embracing the women?

Washington, September 17. OTIS T. MASON.

SCIENCE IN THE MAGAZINES.

AMONG the articles of scientific interest in the magazines received by us, is one in the *Contemporary Review*, in which Prof. Weismann replies to Mr. Herbert Spencer's attack upon his views as to the distinction in the Metazoa between somatic and reproductive cells, and on the immortality of the latter, and of unicellular organisms. With regard to the experiments that have been made with a view to proving the occurrence of telegony, Prof. Weismann says:—

Herr Lang, of Stuttgart, has for twenty years experimented with dogs, without, however, ascertaining "a single fact that could be made use of for the advancement of the infection theory." Of course, in such a case negative results prove nothing; and the attempt must be made to determine the truth by new experiments. But as hitherto there have been no positive results from the observations that have been made; and as the most competent judges, namely, breeders who have a scientific knowledge, such as Settegast and Nathusius, and the late head of the Prussian Agricultural Station at Halle, Prof. Kühn, spite of their extensive experience in breeding and crossing, have never known a case of telegony, and therefore have great doubt as to its reality; it seems to me that *according to scientific principles, only the conformation of the tradition by methodical investigation, in this case by experiment, could raise telegony to the rank of a fact.*

In "A Note on Panmixia," Dr. Romanes attempts to remove any doubt that may exist in Mr. Spencer's mind as to whether Panmixia is a *vera causa* of degeneration, by showing that there are not excessive *plus* variations of an organ. Mr. Spencer had said, "If there are not excessive *plus* variations, the hypothesis of Panmixia is valid"—*ergo*, accepting Dr. Romanes' proofs, the doctrine is triumphant.

Mr. Robert H. Scott writes on "Weather Forecasts" in the *New Review*. He describes the difficulties that beset the weather prophet on all sides, and the various proposals that have been made for gathering in information which would increase their trustworthiness. Some of the proposals, *e.g.* the mooring of signal-ships in mid-Atlantic, are purely visionary, and intelligence directly received from stations in the United States or Canada is practically useless, for the condition of the atmosphere is constantly changing, and the rates at which storms cross the Atlantic vary considerably. The fact that the storms that visit us pass to the northward of the Azores would render those islands of little use to the Meteorological Office, even if a cable were laid to them; and all anticipations as to the advantages to be derived from mountain observatories remain unfulfilled, according to Mr. Scott. However, an examination of the results of forecasts prepared at 8 p.m. from 1879 to 1891 is fairly satisfactorily. Taking the eleven districts of Great Britain and Ireland, for which forecasts are made, it appears that, during the period mentioned, an average of 45·5 per cent. of the forecasts were entire successes, and 34·8 partial, thus giving a total of 80·3. Of the failures, an average of 6·6 per cent. were total and 13 per cent. partial. England (South) showed the highest rate of fulfilment, viz. 85 per cent., counting entire and partial successes together. "The least successful districts are, in order of their figures, the West of Scotland, the South of Ireland, and then the North of Ireland, and the North-west of England. The least successful forecasts are therefore our exposed west and north-west coasts."

Other articles of a scientific character in the *New Review* are: "Are we Prepared to Resist a Cholera Epidemic?" by Mr. Adolphe Smith, and "The Increase of Cancer," by Mr. H. P. Dunn.

Under the title "Atoms and Sunbeams" Sir Robert Ball gives, in the *Fortnightly Review*, a description of Helmholtz's shrinkage theory of the maintenance of the sun's heat, with particular reference to the "precise *modus operandi* by which, as the active potential energy vanishes, its equivalent in available heat appears." "Electric Fishes" is the subject of an article by Dr. McKendrick, and in it we find the investigations carried out by Fritsch, Bois-Reymond and Sachs, Burdon-Sanderson, and Gotch explained in an interesting manner. Before describing the minute structure of individual electrical organs the author makes the following remarks:—

About fifty species of fishes have been found to possess electrical organs, but their electrical properties have been studied in detail only in five or six. The best known are various species of *Torpedo* (belonging to the skate family), found in the Mediterranean and Adriatic Seas; the *Gymnotus*, an eel found in the lagoons in the region of the Orinocco, in South America; the *Malapterurus*, the rääsh, or thunderer-fish, of the Arabs, a native of the Nile, the Niger, the Senegal, and other African rivers; and various species of skates (*Raia*) found in our own seas. It is curious that the Nile is rich in electrical fishes, several species of pike-like creatures (*Mormyrus* and *Hyperopisus*) possessing electrical organs the structure of which has been quite recently investigated by Fritsch. The electrical fishes do not belong to any one class or group, and some are found in fresh water, while others inhabit the ocean.

Two distinct types of electrical organs exist. One is closely related in structure to muscle, as found in the torpedo, gymnotus, and skate, while the other presents more of the characters of the structure of a secreting gland, as illustrated by the electric organ of the thunderer-fish. Both types are built up of a vast number of minute, indeed microscopical, elements, and each element is supplied with a nerve fibre. These nerve fibres come from large nerves that originate in the nerve centres—brain, or spinal cord—and in these centres we find special large nerve-cells with which the nerve fibres of the electric organ are connected, and from which they spring. We may, therefore, consider the whole electric apparatus as consisting of three parts: (1) electric centres in the brain or spinal cord; (2) electric nerves passing to the electric organ; and (3) the electric organ itself. It must not be supposed, however, that the electricity is generated in the electric centres, and that it is conveyed by the electric nerves to the electric organ. On the contrary, it is generated in the electric organ itself, but it is only produced so as to give a "shock" when it is set in action by nervous impulses transmitted to it from the electric centres by the electric nerves.

The *Humanitarian* contains a revised form of the paper on "Cremation" read at the Edinburgh meeting of the British Institute of Public Health by Sir Spencer Wells.

Mr. Geoffrey Winterwood writes on "Mars as a World" in *Good Words*, his article being based in the main upon Camille Flammarion's recent work on Mars and its conditions of habitability. The article is brightened by nine excellent illustrations. "The Cold Meteorite" is the title of a poem by Mr. W. R. Huntingdon in the *Century Magazine*. The meteorite is thus apostrophised:—

"far better 'tis to die
The death that flashes gladness, than alone
In frigid dignity to live on high;
Better in burning sacrifice be thrown
Against the world to perish, than the sky
To circle endlessly, a barren stone."

HYDROPHOBIA STATISTICS FOR 1892 *AT THE INSTITUT PASTEUR.*

An account of the anti-rabic vaccinations undertaken last year in the Pasteur Institute in Paris has been recently published (*Annales de l'Institut Pasteur*, vol. vii. p. 335, 1893). From the statistics here given it appears that no less than 1790 persons underwent this treatment during the past year in Paris alone, and that out of these only four subsequently died from rabies. In 600 of these cases the bites were attributed to animals suspected of suffering from hydrophobia at the time, but in all the others the certainty was established by subsequent veterinary examination, as well as by the death from rabies of other animals bitten by the animal in question.

Since the beginning of the Pasteur treatment in 1886, the mortality from bites on the head after treatment is stated as 1·48 per cent., from wounds on the hands 0·55, and 0·24 per cent. from bites on the limbs.

Thus by far the most serious cases are those in which the head is attacked, and it is pointed out how unfortunate is the delay which frequently occurs between the wound and the arrival of the patient for treatment, the interval militating most seriously against the success of the subsequent inoculations.

The following table indicates the nationality of the patients admitted to the Institute during the past year:—

England	26	Russia	1
Belgium	11	Switzerland ...	3
Egypt	12	Holland	14
Spain	14	India	9
Greece	19	France and Algeria	1584
United States ...	1		
Portugal	96		

Algeria is specially mentioned as being amongst those districts from which the largest number of cases are yearly sent to the Institute.

Last year a patient came from Madeira, rabies having been imported for the first time into the island by a dog from Portugal.

A most unusual occurrence is drawn attention to, viz. the death of a patient, a young Englishman, treated in 1887, and who died last year, five years therefore later, of rabies. Such an exceptional case has not been met with since the commencement in 1886 of the anti-rabic inoculations, which up to the present number 12,782.

Taking the average of cases received during the past six years, rabies appears to reach a maximum in the spring and a minimum in the autumn.

NOTES.

The Harveian Oration will be delivered by Dr. P. H. Pye-Smith, at the Royal College of Physicians, at four o'clock on Wednesday, October 18.

The vacancy in the Mineralogical Department of the British Museum, occasioned by the death of Mr. Thomas Davies, has been filled by the appointment by the trustees of Mr. Leonard J. Spencer, of Sidney Sussex College, Cambridge, who gained the first place at the competitive examination.

Through the munificence of Mr. F. Duncane Godman, F.R.S., a botanical exploration of the island of St. Vincent was made by Mr. Herbert H. Smith and Mr. G. W. Smith in 1889 and 1890. The plants then collected, and those from St. Vincent previously in the Kew Herbarium, have now been arranged, and the resulting catalogue constitutes the *Kew Bulletin* for September (No. 81). All the 977 plants collected by the Smiths are included, whether indigenous or naturalised, and, in addition, 179 flowering plants and 24 ferns not collected by them. We read that, "with regard to the general distribution of the indigenous plants, the principal points are the wide geographical range of the majority, and the smallness of the endemic element, conditions that obtain throughout the whole chain of islands from Tobago to the Virgin group, which are in striking contrast to the proportions of the endemic element in Cuba and Jamaica. . . . . The fern vegetation is very rich and varied, and, in relation to the area, far in excess as to number of species to that of New Zealand, which is generally regarded as one of the most highly concentrated."

We learn from the *Pioneer Mail* that Mr. Dallas, Assistant Meteorological Reporter to the Government of India, leaves shortly for Madras, in order to assist the authorities in starting a daily weather report in that Province.

Dr. Henry B. Ward, of Michigan University, has been appointed Associate Professor of Zoology to the University of Nebraska, Lincoln, Nebr.

Dr. E. Symes Thompson will lecture upon the voice, at Gresham College, Basinghall Street, on October 10, 11, 12, and 13. The lectures are free to the public, and commence each evening at six o'clock.

A very brilliant meteor was seen about 9.45 last night at Leicester (says the *Times* of October 2). It seemed to burst from near the zenith, and proceeded towards the western horizon, increasing very rapidly in brilliancy, until the ground and atmosphere were lit up so that objects in the landscape could be clearly seen at a long distance for several seconds. Mr. H. Cook, of the Birmingham and Midland Institute, says that the meteor was also seen at Neen Sollars, near to Cleobury Mortimer, Salop, at the above-mentioned hour.

Dr. O. Loew, of Münich, well known for his investigations of the nature of protoplasm in connection with Dr. T. Bokorny, has been appointed Professor of Agricultural Chemistry in the University of Tokio, Japan; and Dr. D. Brandis, a fellow of our Royal Society, Professor of Forestry in the University of Bonn.

In two recent numbers of the *Botanisches Centralblatt* is a detailed account, by Dr. F. v. Herder, of the Herbaria and Botanical Museums in St. Petersburg. Of these, five in number besides private collections, the richest and most important are those of the Imperial Academy of Sciences and of the Imperial Botanical Garden.

THE Natural History Society of Danzig has offered a prize of 1000 marks for the best essay on the best means of producing and spreading fungus-epidemics for the destruction of insects injurious to the forests in Western Prussia. The essays must be written in German or French, and are to be sent in before the end of the year 1898.

The numbers of the *Œsterreichische Botanische Zeitung* for August and September contain interesting reports of the botanical excursion of Dr. E. von Halácsy in the Pindus range in Greece, and of that of Dr. J. Bornmüller in Persia. Dr. Bornmüller describes the flora of the neighbourhood of Bushire in March as being especially rich and beautiful.

A SUBTROPICAL botanical laboratory has been established at Eustis, Florida, under the direction of Prof. Swingle. The diseases of fruits belonging to the *Aurantiaceæ* are a special subject of investigation.

THE singular swarms of flies observed by Mr. R. E. Froude at the end of May last, and described by him in these columns (vol. 48, p. 103 and p. 176), have also been seen at Muskegon, Michigan, by Mr. C. D. McLouth. Writing from that city to *Science* of September 15, Mr. McLouth says that on the evening of June 26 the fire brigade was called to two of the highest buildings, the alarms being caused by an appearance as of smoke issuing from the pinnacles of the towers. In both cases the appearance was found to be caused by clouds of insects. Some insects afterwards captured and supposed to be identical with the swarmers were found to be Neuropters.

THE fiftieth volume of the *Verhandl. des Naturhistor. Vereins der preuss. Rheinlande* contains numerous short notices on various subjects, and three important memoirs:—B. Stürtz, on star-fishes, giving a bibliography of recent and fossil forms, notes on classification and distribution, and descriptions of three new species; a continuation of the monograph, by A. Hosius, on the Foraminifera of the Miocene; and a paper by H. Laspeyres on the nickel ores and minerals of the Rhenish rocks, giving numerous analyses and crystallographic notes.

MR. G. CHRISTIAN HOFFMANN has prepared an excellent catalogue of Section I. of the Museum of the Geological Survey of Canada. It embraces the systematic collection of minerals and the collections of economic minerals and rocks and specimens illustrative of structural geology. Reference is facilitated very considerably by four very full indexes. The first of these is an index to the cases containing the minerals; the second to the numbers borne by the specimens; the third to mining districts, areas, camps, locations and claims, mines, quarries, and pits, and the fourth to subjects. Since all the specimens are from Canadian localities, Mr. Hoffmann's catalogue may be taken as a representation of the mineral resources of the Dominion.

THE modifications in the physiological character of micro-organisms which may be produced by either natural or artificial means, and which may, moreover, become inherited and permanent, is one of the most fascinating subjects in bacteriology. But it opens up a problem of much importance in the identification of bacteria, for the characteristic appearance may become so modified that its original parentage is with difficulty recognised. In this connection the production of a race of *sporeless* anthrax, endowed with the same virulent properties, resembling also microscopically the original form, is of particular interest. Such "asporogène" anthrax was first produced by Chamberland and Roux, through the addition of small doses of potassium dichromate to broth infected with anthrax-blood. By this means a generation of anthrax bacilli was obtained in which the power of producing spores was permanently destroyed. Since the publication of the above, "asporogène" anthrax has been obtained by other investigators, whilst Lehmann came upon such a variety quite accidentally in an old gelatine culture. Still more recently (*Le Bulletin Méd.* p. 293, 1892), Phisalix has succeeded in producing sporeless anthrax by the continuous and successive cultivation of anthrax bacilli at 42° C. For the original infection the blood of a sheep dead of anthrax was taken, and portions of this culture were transferred to a second culture, and also kept at 42° C., this process being continued for twenty-five generations covering a period of five months. The twelfth generation already yielded a variety incapable of producing spores except on being first passed through the body of a mouse, but the fourteenth generation had established a race permanently incapable of producing spores. These asporogène cultures, however, unlike those of Chamberland and Roux, suffered an attenuation of their virulent properties, and the descendants of the twentieth generation were absolutely harmless as regards animals. The possibility, therefore, of pathogenic microbes losing their virulence, or of harmless saprophytes being trained up to acquire pathogenic properties, is one which must without doubt be taken into consideration; and when we remember that sunshine alone may produce such modifications in the physiological characters of microbes as to permanently deprive certain pigment-producing bacteria of this property, and raise up instead a colourless race (Laurent), the indulgence of this possibility becomes yet more within the bounds of legitimate conception.

THE Meteorological Reporter to the Government of India has published No. 5 of *Cyclone Memoirs*, containing an elaborate and valuable discussion, accompanied by twenty-five plates, of three cyclones in the Bay of Bengal and Arabian Sea during the month of November, 1891. The first storm, called the Port Blair cyclone, originated in the Gulf of Siam on October 29 and 30, and caused great destruction of life and property in the South Andaman Island. It is the first large storm for which there is conclusive evidence that it originated outside the area of the Bay of Bengal, and owing to its rapid recurvature several ships encountered the storm twice; it was probably owing to this that the pilot vessel *Coleroon* foundered. An examination of the storms which have occurred since 1737, shows that not more than three or four of them could possibly have advanced across the Malay Peninsula into the bay. The second storm originated on the 1st and 2nd, between the Maldives and the Travancore coast, and is said to be the most violent that has been experienced in Minicoy for the past quarter of a century. This storm is the more interesting from the fact that exact information is rarely obtained of the birth of such a disturbance in the neighbourhood of the equator. The predominant feature was the excessive amount of rainfall, which was quite as exceptional as the storm itself. The third storm originated in the south-east of the bay, on the 19th and 20th; it was remarkable only for its track, as it advanced by a curved path into Central Burma, instead of to the coast of Madras, as usual. The tracks of this and of the first storm show certain abnormal conditions to have existed during the whole of the month. All the disturbances were generated in the humid south-west monsoon current, and were apparently not due to any mechanical action between two opposite air currents. Mr. Eliot states that rainfall appears to be the dominating factor in all large cyclones in India, and that this or aqueous vapour was the chief agent in determining the origin and motion of the three storms above referred to.

A REMARKABLE case of resuscitation of an optical image is described from personal experience by Prof. T. Vignoli in a paper recently communicated to the *Reale Instituto Lombardo*. On the morning of July 3, after a railway journey in a bright sun, and two days' walk in a suffocating heat, he happened to be in a room with several other persons, and during conversation looked at a balcony bathed in bright sunlight, but without taking any special interest in it. The balcony was decorated with trellis-work and ivy. Flowering creepers were arranged in vertical columns, each column being crossed below by the iron bars of the balcony, and above by sticks supporting the plants. A cage with birds hung up in the middle. Two days afterwards, very early in the morning, the professor was in bed, but perfectly awake, and in ordinary health, when, to his astonishment, he saw on the ceiling, by the light coming through Venetian blinds of two large windows, an exact reproduction, in all its colours and details, of the balcony referred to. The phenomenon lasted long enough to permit some detailed investigation. On closing the eyes, the image disappeared, to appear again when they were opened. It was unaffected by regarding it with each eye alternately. A finger placed between the eye and the image intercepted it in the same manner as it would any ordinary object; in short, the phenomenon obeyed all the optical laws of vision. And not only was the cage of birds reproduced, but also its swinging motion noticed before. Prof. Vignoli argues that this cannot have been a case of ordinary hallucination, since the latter is unaffected by the opening or closing of the eyes, and is practically limited to occasions of abnormal health or disturbed state of mind. It must be regarded as an outward projection of a recollected image, though the mechanism of this projection does not appear to be well understood by the professor himself. A case such as this, of what the German psychologists would call *wach-traum*, merits the attention of those interested in psycho-physics.

The current number of the *Electrical Review* contains a description of some of the latest appliances in "electric heating" for domestic use. In the cookery experiments at the Crystal Palace last year the efficiency obtained was, as a rule, very small, and the wires used in the apparatus were soon destroyed. Mr. Binswanger, of the General Electric Company, claims to have got over both these drawbacks, as well as that of the difficulty of insulation. Instead of wrapping the wires in asbestos, mica, &c. (under which conditions they rapidly oxidise), or clothing them with enamel (which cracks at high temperatures), a cement is applied in a cold state, which is said to insulate well without cracking, even at very high temperatures. The "electric kettle" has a copper bottom resting on a double layer of silicate cement, between the two parts of which the copper wires carrying the current are arranged. The 1 pint size takes 3 amperes at 100 volts to raise the water to boiling, and as the time required to raise a pint of water from 15° C. to 100° C. by an expenditure of 1000 watts is 3·7 minutes, this kettle, which is a "300-watt kettle," will take 12 minutes to boil 1 pint. With electricity at 4d. per unit, the cost of boiling the pint of water would be approximately one farthing, which is, of course, much dearer than gas. Stew-pans, ovens, and "radiators" for heating rooms are also made, as well as frying-pans and gridirons, in the two last-named of which greater economy is practicable than in the other cases, as the heat can be produced in the exact spot in which it is wanted. Altogether it is evident that although the use of "electric heating" for domestic culinary purposes is not yet in its really practical stage, it is well on the way there.

In the course of an interesting series of articles in *Electricité* on the "Electric Lighting of Trains," we find the following figures given as a comparison between the cost of oil-lamps and electric lights. The system under discussion is that of accumulators carried in the train and charged at fixed charging stations. The total expense of an electric-lamp in a first-class carriage, including interest on capital, &c., comes out at 0·0289 francs per "lamp-hour," while an oil-lamp (of only 7-candle power) comes to 0·38 francs per hour, while in the second and third class carriages, where more lamps are run off the same battery, the comparison is still better in favour of the electric system.

A catalogue of works on Phanerogams, alphabetically arranged in genera, has been issued by Messrs. Dulau and Co.

Two pamphlets by Sir Spencer Wells have been sent to us—one, "The Prevention of Preventible Disease," is a lecture delivered in Glasgow in May last, and the other, "Cremation and Cholera," is reprinted, with additions, from the *Forum* for February, 1893. They both deserve a wide circulation and attentive reading.

Messrs. Cassell and Co. have just published a new edition of "Elementary Lessons with Numerical Examples in Practical Mechanics and Machine Design," by R. G. Blaine. The book has been to a large extent rewritten, and contains a good deal of additional matter, an attempt having been made to bring the work up to date.

There is little of scientific value in Mr. Phil Robinson's latest volume—"Some Country Sights and Sounds" (Unwin). The author, however, writes pleasantly enough on a variety of topics more or less to do with the country.

We have received a volume containing the meteorological observations made at the Adelaide Observatory and other places in South Australia and the northern territory, during the years 1884–5, under the direction of Sir Charles Todd, F.R.S.

A new edition (the eighth) of Valentin's "Course of Practical Chemistry, or Qualitative Chemical Analysis," edited and revised by Prof. W. R. Hodgkinson, has just been published by Messrs. J. and A. Churchill. A few additions have been introduced into the work, including an extra chapter, in which quantitative operations are dealt with.

The June number of *Timehri*, the journal of the Royal Agricultural and Commercial Society of British Guiana, has just appeared, and contains articles on "The Seasons in Guiana," "Notes on a Journey to a Portion of the Cuyuni Gold Mining District," and "Amateur Insect Collecting in British Guiana," occasional notes, reports of the society's meetings, &c. It may be obtained in London from Mr. Stanford.

Messrs. Blackie and Son have just published an attractive little book entitled "Animal and Plant Life," by the Rev. Theodore Wood. The book is the sixth number of a useful series of science readers adapted for use in elementary schools.

"Weissmann's Theory of Evolution" (1893) is the title of an article by Prof. Romanes in *The Open Court* of September 14. Prof. Weismann's recent modifications of his sequent theory of evolution are the chief points discussed.

A list of Coleoptera, prepared by Mr. James Edwards, and forming Part XII. of the "Fauna and Flora of Norfolk," has been reprinted from the Transactions of the Norfolk and Norwich Naturalists' Society (Vol. V.), and issued separately.

Under the title "Les Moteurs à Gaz et à Pétrole" (Gauthier Villars), M. Paul Vermand gives an excellent summary of the present state of knowledge of atmospheric motors. The volume belongs to the Aide-Mémoire series. Another work in the same series that has recently been received is "Décoration Céramique au Feu de Moufle," by M. E. Guenez.

Messrs. Methuen and Co.'s Commercial Series, "intended to assist students and young men preparing for a commercial career, by supplying useful handbooks of a clear and practical character, dealing with those subjects which are absolutely essential in a business life," has received an addition by Mr. H. De B. Gibbins, entitled "British Commerce and Colonies."

A SECOND edition of Mr. J. R. Ainsworth Davis' "Elementary Text-book of Biology" (Messrs. Charles Griffin and Co.) having been called for, the book has been thoroughly revised and much enlarged, and a number of illustrations have been added. Part II. (Animal Morphology and Physiology) has had its value enhanced by the addition of a chapter on the Distribution of Animals.

MESSRS. WHITTAKER's library of popular science has received an addition in the form of a volume entitled "Electricity and Magnetism," by Mr. S. R. Bottone. The illustrations in the book are a little coarse, but are just what a teacher requires to elucidate the text. Mr. Bottone is evidently at home in his subject, and he knows the way to present it to the general reader.

DR. J. W. GREGORY has conferred a benefit upon students of petrography by translating the "Tables for the Determination of the Rock-Forming Minerals," prepared by Prof. F. Lœwinson-Lessing. The tables of Rossenbach and Michel Lévy and Lacroix leave nothing to be desired in the matter of completeness, but they are of little use to the elementary student for purposes of identification. By means of the synoptical tables, however, the commoner rock-forming minerals can easily be determined when their characters have been microscopically observed. A very suitable introduction to the tables is a description of the petrological microscope, by Prof. Grenville A. J. Cole. Messrs. Macmillan are the publishers of the translation.

THE October number of *Natural Science* is of unusual interest. Among the articles are the following: "The Effect of the Glacial Period on the Fauna and Flora of the British Isles," by G. W. Bulman; "Some Recent Researches on the Habits of Ants, Wasps, and Bees," by George H. Carpenter; and "The Recent Plague of Wasps," by Oswald H. Latter. Dr. C. Herbert Hurst theorises upon "The Digits in a Bird's Wing," and Mr. J. T. Cunningham upon "The Problem of Variation." In addition there are numerous notes and book-notices.

AN investigation of the composition and properties of the dangerously explosive iodide of nitrogen has been carried out by Dr. Szuhay in the laboratory of the University of Buda-Pesth, and an account of his interesting experiments is contributed to the latest publication of the *Berichte*. A large number of investigators have previously attacked this somewhat fascinating subject, but the knowledge hitherto accumulated has been insufficient to enable us to express with certainty its composition. One of its properties, its unparalleled readiness to explode with or without provocation, has been so much to the fore as to almost entirely exclude investigation of its more important, although less sensational, chemical properties. One variety of the substance, which was obtained by Dr. Szuhay by adding ammonium hydrate solution to powdered iodine, was found to be so pre-eminently disposed to detonative decomposition that it frequently exploded even under water, and if it were successfully transferred while wet to a filter it exploded upon the passage of the first draught of air. An attempt to ascertain its composition by careful decomposition with sulphurous acid resulted in the complete pulverisation of the containing vessel. Iodide of nitrogen was first prepared by Curtois by mixing alcoholic solutions of iodine and ammonia. He considered it to be the tri-iodide NI_3, an opinion which was subsequently shared by Gay Lussac. Millon and Marchand afterwards expressed the view, unsupported, however, by experimental evidence, that it contained hydrogen, and might be represented by the formula NH_2I. More recently Bineau, and in this country Dr. Gladstone, have adduced more trustworthy evidence, from its mode of decomposition by an aqueous solution of sulphuretted hydrogen and by sulphurous acid, that this extraordinary substance does indeed contain hydrogen, but only to the extent of one atom, its constitution being NHI_2. Bunsen, however, subsequently communicated to the *Annalen* the view that iodide of nitrogen consists of NI_3, but that according to its mode of preparation it contains more or less ammonia. Finally, Stahlschmiedt has brought forward the further hypothesis that when an alcoholic solution of iodine is mixed with aqueous ammonia the substance NI_3 is produced, but that when alcoholic ammonia is employed the product possesses the composition NHI_2. The result of all this conflicting testimony has been to leave the question of the composition of iodide of nitrogen an open one.

IODIDE of nitrogen was prepared by Dr. Szuhay, after investigating most of the methods hitherto described, by adding excess of aqueous ammonia to a concentrated solution of iodine in potassium iodide. It is thus obtained in the form of a very fine powder, which was found to be capable of safe purification by washing with a dilute solution of sodium sulphate. It is requisite to protect the filter from draughts of air which are liable to induce explosion. The purified substance, of course in a moist condition, as it cannot be dried without explosion, was analysed by decomposition with a solution of sulphurous acid of known strength and estimation of the amount of iodine and ammonia in the solution. Its composition was indubitably proved to be NHI_2, thus confirming the earlier work of Dr. Gladstone and of Bineau. This conclusion is powerfully supported by the fact that Dr. Szuhay has been able to prepare a silver derivative of the compound by replacing the hydrogen atom by silver. This silver compound is readily obtained by adding powdered oxide of silver or an ammoniacal solution of silver nitrate to iodide of nitrogen suspended in water. It is a black flocculent substance which is quite as explosive as iodide of nitrogen itself. When carefully dried the least rise of temperature provokes explosion. It also detonates upon being struck or even when brought into gentle friction with any other substance. When warmed under water, or when treated with dilute acids it is quietly decomposed, silver iodide being deposited, free iodine liberated, and free nitrogen escaping with effervescence. The relative amounts of these products of decomposition conclusively prove the compound to possess the composition $AgNI_2$. Moreover, considerable evidence is also adduced to show that potassium, sodium, and barium replacement compounds are capable of existence in solution. The existence of the compound HNI_2 is thus fully demonstrated, and whether or not the compounds NI_3 and NH_2I are likewise capable of formation under different experimental conditions is a question which doubtless further work will elucidate. It is not unworthy of notice that there is a considerable amount of resemblance between this extraordinarily explosive substance and the similarly distinguished azoimide $H-N\Big\langle\begin{matrix}N\\ \|\\ N\end{matrix}$; for both contain the imido group NH the hydrogen of which is capable of being replaced by silver and other metals, and both appear in consequence to be endowed with a somewhat acid nature by the two atoms of negative iodine in the one case, and the negative diazo-nitrogen group in the other.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Annelids *Myrianida maculata* (one of these with a chain of buds), *Sphærodorum peripatus* and *Siphonostoma uncinatum*, the tubicolous Gephyrean *Phoronis* *hippocrepia*, and the Decapod Crustacean *Athanas nitescens*. The floating fauna has presented hardly any appreciable change: numbers of young *Geryonia appendiculata*, some Margelid medusæ and swarms of *Obelia*, have formed the chief Cœlenterate element. *Noctiluca* is generally present in fair quantity. The Ascidian *Ciona intestinalis* is now breeding.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mr. Duncan Mackintosh; two Lions (*Felis leo*, ♀♀ jew.) from Somaliland, presented by The Lord Delamere; four Long-fronted Gerbilles (*Gerbillus longifrons*) from Tunis; two Long-tailed Field Mice (*Mus sylvaticus*) from France, presented by Mons. Albert de Lautreppe; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. H. Rich; two White Storks (*Ciconia alba*) European, presented by Mr. Walter Winans, F.Z.S.; an Adelaide Parrakeet (*Platycercus adelaidæ*) from Australia, presented by Mrs. Waterhouse; two Common Sheldrakes (*Tadorna vulpanser*) from Scotland, presented by Mr. Francis Alexander; three Dwarf Chameleons (*Chamæleon pumilus*) from South Africa, presented by Mr. Henry Beamish; an Alligator (*Alligator mississippiensis*) from Florida, presented by Mr. H. Venn; a Serval (*Felis serval*), a Cape Crowned Crane (*Balearica chrysopelargus*), a Secretary Vulture (*Serpentarius reptilivorus*), a Black-winged Kite (*Elanus cæruleus*) from South Africa, a Grey Squirrel (*Sciurus cinereus*) from North America, deposited; three Viscachas (*Lagostomus trichodactylus*), a Hairy Armadillo (*Dasypus villosus*), two Ypecaha Rails (*Aramides ypecaha*), a Great Grebe (*Æchmophorus major*) from South America, a Prêtrés Amazon (*Chrysotis pretrii*) from Brazil, purchased; four Indian Wild Swine (*Sus cristatus*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ON THE PARALLAX OF THE PLANETARY NEBULA B.D. + 41°.4004.—During the summer of 1892 Dr. J. Wilsing began a series of photographs of Webb's planetary nebular B.D. + 41°.4004, using the new photographic refractor of the Potsdam Observatory, with the intention of determining the parallax. In the current number of *Astronomische Nachrichten* (No. 3190) he gives an account of the measurements made. The undertaking seems to have been especially difficult on account of the numerous errors that were liable to arise, and also to the lack of sharpness of the image of the nebula on the photographic plate. From June 1892 to June 1893 he obtained thirty-four plates with two exposures on each of eight minutes duration, and they were all measured with the Repsold's measuring apparatus, a description of which instrument is given in vol. v. of the Publications of the Potsdam Astrophysical Observatory. Six stars were used for comparison, and the distance of the nebula was measured from two of these stars, the others being used for finding the value in seconds of arc of the measured distances, &c. The distances measured show a distinct decrease, as will be gathered from the following table, when N. 3 and N. 6 denotes the distances from the two companion stars respectively:—

1892-93.	N. 3.	N. 6.	Wt.
	′ ″	′ ″	
June 25	7 24·53	13 9·72	$\frac{2}{3}$
July 13	24·40	9·77	1
Aug. 8	24·53	9·56	$\frac{1}{3}$
Sept. 23	24·42	9·71	$\frac{1}{3}$
Oct. 18	24·43	9·61	1
Nov. 10	24·23	9·60	$\frac{4}{3}$
Jan. 2	24·32	9·43	$\frac{1}{3}$
June 5	7 24·56	13 9·61	$\frac{1}{3}$

Assuming the nebula distances from these stars as 7′ 24″·40 + 13′ 9″·60 for 1892·0, the position, corrections, relative yearly proper motions, and the relative parallaxes, when taken into account, gave the following numbers for the equation, observed—calculated

O – C.

N. 3.	N. 6.	N. 3.	N. 6.
″	″	″	″
+ 0·05	+ 0·05	+ 0·06	– 0·05
– 0·07	+ 0·06	– 0·13	+ 0·01
+ 0·08	– 0·11	– 0·05	– 0·08
+ 0·02	+ 0·03	0·00	+ 0·05

The negative relative parallax thus obtained shows, as Dr. Wilsing in his concluding remarks says, that the distance of Webb's nebula from the sun cannot be assumed in any way to be less than the distances of both the eleventh-magnitude comparison stars.

SOLAR AND LUNAR EPHEMERIS FOR TURIN.—In vol. xxviii. of the *R. Accademia delle Scienze di Torino*, Dr. Alberto Manaira contributes the ephemerides of the sun and moon which he has calculated out for the horizon of Torino for the year 1894. For each day of the month throughout the year he gives the time of rising, meridian passage, and setting of the sun and moon. Brief reference is also made to the eclipses visible in that year, giving the time (mean time Rome) of the chief contacts.

GEOGRAPHICAL NOTES.

THE *Mouvement Géographique* publishes a sketch map of Dr. Baumann's exploration to the north-east of Lake Tanganyika, in the country of Urundi. He has traced out the head waters of the Kagera, which take their rise close to Tanganyika and flow down the long slope to the Victoria Nyanza, being thus the ultimate source of the Nile, if it is possible to apply that name to any of the streams which feed Lake Victoria. The mountains between the basin of the Kagera and that of the Rusiji are called by the Warundi *Misozi a Mwedi*, or Mountain of the Moon. Some of the summits were apparently abou 10,000 feet above the sea. The Rusiji River, which flows int Lake Tanganyika at its northern end, is represented provisionall as flowing from the reported Lake Oso, which receives the drainage from the southern slopes of the Mfumbiro mountains, the north slope of which drains to Lake Albert Edward. If this topography turns out to be correct, the Mfumbiro range forms the only barrier across the great meridional furrow which runs from the Mediterranean to the Zambesi, and includes Lakes Albert, Albert Edward, the possible Oso, Tanganyika, and Nyasa.

MR. H. F. B. LYNCH, with his brother and a Swiss guide, succeeded, after seven and a half hours' climbing, in making an ascent of Mount Ararat, on September 19, and promises some interesting information regarding his observations on his return to this country. He took some photographs of the mountain scenery.

PRINCE KRAPOTKIN publishes his address on the Teaching of Physiography, given at the Teachers' Guild Conference at Oxford, in the October number of the *Geographical Journal*. He deprecates the exclusive use of the *Heimatskunde* in introducing children to the study of the earth, and approves rather of teaching geography by considering the earth as a whole, insisting, however, on the importance of personal work by the scholars in their own neighbourhood to extend and give reality to theoretical teaching.

AN interesting history of the mapping of the state of Missouri, by Mr. Arthur Winslow, assisted by Mr. C. F. Marbut, has been published in the Transactions of the Academy o Sciences of Missouri. Starting with the dictum that the civilisation of a people is proportional to the accuracy with which their country is mapped, Mr. Winslow traces the gradual improvement of the maps of Missouri in a readable way. He gives rough sketches of the more interesting early maps. Franquelin's map of 1688 is the first on which the name "Missourils" appears, but the river to which the name was applied is very imperfectly drawn. In Sinex's map of 1710 the position of the Mississippi is shown nearly sixty miles too far west, and the mouth of the Missouri twenty-five miles too far north. In du Pratz' map of 1763 the error in both directions is doubled. Lieutenant Ross, of the British Army, in 1765 made a survey of the Mississippi, accurate as to latitudes, but wrong in longitude. The first really effective survey was that of Messrs. Lewis and Clarke in 1804–1806. In 1815 Land Office surveys were commenced. After the admission of the State to the Union in 1820 more accurate surveys were required to fix the boundary lines, but these had to be rectified in 1850, when serious discrepancies were found. Really trustworthy surveying was only begun when the Coast and Geodetic Survey commenced a triangulated line across the state in 1871. The Mississippi and Missouri River Commissioners subsequently rectified the mapping of the rivers, and now the topographical survey of the State is being carried out by the U.S. Geological Survey, which has executed maps of one-third of the area on the scale of about two miles to the inch. The Missouri Geological Survey also makes a topographical map of selected parts of the State on the scale of about one mile to the inch.

THE OBSERVATORY ON MOUNT BLANC.

AS briefly announced in our Notes last week, Dr. Janssen has recently visited the observatory on Mount Blanc. In the current *Comptes Rendus* he gives an account of the expedition from a scientific point of view, and the following is a translation of his description:—

We left Chamonix on September 8, at 7 a.m., and arrived at the summit on September 11, at 2.30 p.m. The observatory was then in front of us. This construction has several floors, of which the framework, formed by large and massive beams crossed in all directions in order to ensure the rigidity of the whole, produces a deep impression upon the mind. One wonders how it has been possible to transport the edifice to this altitude and fix it on the snow. However, if the conditions offered by the hard, permanent, and little mobile snows of the summit are carefully considered, it is soon recognised that the snows are able to support very considerable weights,[1] and that they will be only slightly amenable to displacements, which will render it necessary to straighten again the construction which has been fixed upon them.

On my arrival I made a rapid survey, and saw that the construction had not been sunk in the snow as much as I had stipulated of the contractors. I do not approve of this. My guides and myself then took possession of the largest underground room. I intended at first to fix the instruments for enabling observations to be commenced immediately, and the provisions were left on the Rocher-Rouge. This circumstance put us in a state of perplexity, for the weather suddenly became very bad, and we had to remain two days separated from the stores. The storm lasted from Tuesday until Thursday morning. Beautiful weather then set in, and I was able to begin the observations.

The observations have for their principal object the question of the presence of oxygen in the solar atmosphere. The Academy knows that I worked at this important point during my ascensions to the Grands-Mulets (3050 metres) in 1888, and at M. Vallot's observatory in 1890.

But the novelty of the observations of 1893 lies in the fact that they have been effected on the very summit of Mount Blanc, and that the instrument employed is infinitely superior to that of the two preceding ascensions. At the first, in fact, a Duboscq spectroscope incapable of separating the B group into distinct lines was employed, while the instrument about to be employed at the summit of Mount Blanc is a grating spectroscope (the dispersive piece of which I owe to the kindness of Rowland), with telescopes having a focal length of 0·75 and showing all the details of the B group. This circumstance is of considerable importance, for it may lead to the discovery, in the constitution of the group in question, of valuable elements for measuring in some way the effects of the diminution of the action of our atmosphere as one ascends into it, and, accordingly, to determine whether this diminution corresponds to total extinction at its limits. In fact we shall learn whether or no the double lines which make up the B group diminish in intensity as their refrangibilities diminish; that is, as their wave-lengths increase.

This circumstance may perhaps be employed with profit, if not to measure, at least to observe the diminution of the action of the selective absorption of our atmosphere. It has been ascertained that the most feeble doubles fade away one after the other as the atmosphere is ascended, that is to say, as the absorbing action is diminished. Thus, under ordinary circumstances, at the surface of our seas or upon our plains, thirteen or fourteen doubles can be seen, not reckoning that which is known as the head of B.

But even at Chamonix, that is at an altitude of 1050 metres, the thirteenth double is very difficult to make out, and at the Grands Mulets (3050 m.), it is only possible to see from the tenth to the twelfth, while at the summit of Mount Blanc I could hardly go beyond the eighth.

It is not to be supposed that we establish a proportionality between the numerical diminution of the doubles and that of the atmospheric action. The law is evidently of a much more complex character. But this diminution, especially when considered in connection with the experiments made with tubes full of oxygen, and able to reproduce the series of atmospheric phenomena to which we have referred, is sufficient for us to conclude that the B group would totally disappear at the limits of our atmosphere. It is remarkable, however, that if we take the co-efficient 0·566 that represents the diminution of atmospheric action at the summit of Mount Blanc according to barometric pressures $\left(\frac{0·43}{0·76} = 0·566\right)$ and multiply it by thirteen—the number that represents the doubles clearly visible on the plain—we obtain 7·4 as the result; that is to say, very nearly the number (8) doubles that can be seen by me on the summit of Mount Blanc.

This result is certainly remarkable, but I repeat that, in my opinion, it is only by the comparison with tubes reproducing the same optical conditions as nearly as possible, that any definite conclusions will be obtained. These comparative experiments have already been commenced in the laboratory of Meudon Observatory, and they lead to the same result, viz., the disappearance of the groups A, B, and α at the limits of the atmosphere. On account of the importance of the question, however, the experiments will be repeated and completed.

The question arises as to whether the high temperatures to which solar gases and vapours are subjected are not capable of modifying the power of selective absorption, and particularly whether the absorption of oxygen which takes place in the sun's atmosphere would not be altogether different from that indicated by the experiments which have been made at ordinary temperatures.

I have already instituted experiments with the idea of replying to this objection. I shall give an account of them to the Academy in due course, but I may say that the absorption spectrum of oxygen, either the line spectrum or the unresolvable bands, do not appear to be modified in an appreciable manner when the oxygen is raised to temperatures of about 400 or 500 degrees.

On the whole, I think that observations made on the summit of Mount Blanc give a new and much sounder foundation to the study of the question of the purely telluric origin of the oxygen groups in the solar spectrum, and lead to the conclusions previously stated.

Independently of these observations I have also given some attention to the transparency of the atmosphere of this almost unique station, and to the atmospheric phenomena which are included in such an extensive view, and across such a great thickness. I shall speak of this on a future occasion.

The observatory, of course, is not completed. There yet remains much to be done independently of interior arrangements and the installation of the instruments; but the great difficulty has been overcome, for we are free to work, and no longer have to reckon with the snowstorms; the rest will follow in due course.

I hope that the observatory will soon be able to offer a much more comfortable sojourn than I have had there; but that will depend upon the weather. Be this as it may, I regret nothing. I strongly wished to see our work in position, and still more fervently desired to inaugurate it by observations which are ever in my mind. I am fortunate at having been able to realise my desires in spite of some difficulties.

IRON AND STEEL INSTITUTE.

A VERY successful meeting of the Iron and Steel Institute has just been held in Darlington, commencing on Tuesday, September 26. The President, Mr. E. Windsor Richards, occupied the chair There was a very good list of papers,

[1] See *Comptes Rendus* for an account of experiments made at Meudon on the resistance of slightly compressed snow.

eleven in all, as follows:—On the Manufacture of Basic Steel at Witkowitz, by Paul Kupelwieser; on the Waste of Fuel, Past, Present, and Future, in Smelting Ores of Iron, by Sir Lowthian Bell, F.R.S.; on Iron and Steel at the Chicago World's Fair, by H. Bauerman; on Iron and Steel Wire, and the Development of its Manufacture, by J. P. Bedson; on the Sampling of Iron Ore, by T. Clarkson; on the Tudhoe Works of the Weardale Iron and Coal Company, by H. W. Hollis; on the Lührig Coal Washing and Dry Separation Plant at the North Bitchburn Coal Company's Randolph Pit, by James I'Anson; on Carbon in Iron, by Prof. Ledebur (Freiberg); on Suggested Improvements in connection with the Manufacture of Steel Plates, by William Muirhead; on the Last Twenty Years in the Cleveland Mining District, by A. L. Steavenson; on the Production of Wrought Iron in Small Blast Furnaces in India, by T. Turner.

Mr. Kupelwieser's paper was first taken, and gave an interesting account of the basic process, which the author has introduced with considerable success at Witkowitz. It is of course well known that the cheapest process of steel manufacture is that carried out with the Bessemer converter; the Siemens furnace comes next. Although the basic process was originally devised for the use of the Bessemer converter, it has had considerable application with the open-hearth furnaces. The basic process is, however, dearer than the old acid system of manufacture, and some of the most beautiful mild steel produced is made in the open-hearth furnace with a basic lining. The latter, again, is more costly than the old acid lining, and we have therefore the following gradations as to cost:—First, the acid Bessemer, or original process; next, the basic Bessemer; then the acid open-hearth, and finally the basic open-hearth; the latter being the dearest of the four. It is obvious therefore, that when circumstances permit it, that the Bessemer converter should be used in place of the open-hearth, but there is an objection to the Bessemer converter in the fact that it acts so much more quickly; the slower working open-hearth furnace giving time for tests to be made, and the product is consequently more certain. Mr. Kupelwieser has introduced a combined process in Witkowitz, which many members of the Iron and Steel Institute saw in work, when the Institute meeting was held in Austria. The pig-iron obtained in Witkowitz contains too much phosphorus for use in the ordinary Bessemer process, while it does not contain sufficient phosphorus for the basic process. As a further complication, a supply of cheap scrap was not obtainable at the works. The way in which the author got over his difficulties is highly ingenious, and is well worth study by English steel-makers. The pig-iron is run from the blast furnace into the ladle, and transferred immediately to the converter, which has an acid lining. The blast is then turned on, and the blow kept up till the pig-iron is de-siliconised: an operation that requires about five or six minutes to perform. The silicon being removed, manganese and a considerable amount of carbon remain; the metal is poured into a ladle, and taken to the open-hearth furnace, where the process of steel-making is completed. This method of operation has the great advantage that the molten metal, when run into the open-hearth furnace, which is basic lined, does not destroy the lining, as it has become completely de-siliconised. The time required for working the charge is considerably diminished, and the amount of iron taken up by the slag is said to be less, as also are the expenditure of fuel and cost of wages. We do not propose following the author into his figures as to the cost of production, but the balance in favour of his method is 10*s.* per ton as compared with the cost of conversion in the open-hearth furnace from the commencement, whilst it is said to be no dearer than the basic Bessemer process when carried out on a large scale. Perhaps the chief point of interest to English steel-makers is the working of the metal from the blast furnace direct; a thing which has of course often been considered by steel-makers in all parts of the world. It is always difficult, and often fallacious, to make comparisons unless the whole conditions on both sides be similar, and it is certain that those conditions existing at Witkowitz have not their exact counterpart in this country. It is not surprising, therefore, to find that during the discussion of the paper high authorities differed. Mr. James Riley did not by any means approve of the author's suggestions; basing his objection principally on the waste that would take place in the process. On the other hand, Mr. Snelus and Mr. Whitwell—both high authorities—supported the author. There is of course the undeniable 10*s.* a ton, which is sufficient vindication of the process as carried out in Witkowitz. Whether the 10*s.* would still be to the good in English steel works, is a matter that is open to question.

Sir Lowthian Bell next read a paper on the waste of heat, past, present, and future, in smelting iron ores. This contribution was largely of a historical nature. Its scope is sufficiently indicated by the title, and it would be a useful intellectual exercise for students to follow its reasoning.

Mr. Bauerman's paper on the iron and stsel exhibits at the Chicago Exhibition was of the usual nature of such papers. The principal wonders to be seen were referred to by the author, but it is unnecessary for us to follow him in his description. The same remark applies to Mr. Steavenson's paper, with the reading of which the first day's sitting was brought to a close. In the afternoon a very instructive and pleasant excursion was made to the Weardale Steel and Iron Company's works at Spennymore, where members had an opportunity of seeing the gigantic operation of cogging and rolling ingots, which are characteristic of the modern steel works.

The first paper taken on the second day's sitting was Prof. Ledebur's contribution on carbon in iron. This met with a mixed reception, the opinion of some members appearing to be that it was hardly worthy of the time allotted to it, although international courtesy forbade them blankly saying so. We think such an opinion can only be due to a cursory study of the paper, which appears to be one of considerable value, and especially suitable for the Transactions of the Institute. There is some controversial matter in this memoir, but its value is that it brings together in a very compact form many of the leading facts involved in the subject upon which it treats, and although there is not much in it that is new—in fact, the matter consists of that already known—yet many of the details are, as was stated by Mr. Hadfield, the result of the author's own research. The paper is well worth the consideration of metallurgists, and we think there are few who would not benefit by their memories being refreshed, even if the facts were not altogether new. Prof. Ledebur holds that there are four states of carbon in iron. The first is the graphitic state; the second, that which the author described as the temper-carbon; the third is a carbide carbon or cement carbon; and the fourth hardening carbon. It will be evident that in stating this the author opened up matter largely of a controversial nature, and in the discussion which followed, Mr. Snelus, Mr. Hadfield, Prof Roberts-Austen, Mr. Stead, Sir Lowthian Bell, Prof. Thomas Turner, and Mr. Edward Riley took part. It is unnecessary to say that with all these gentlemen engaged in the discussion there was some clashing of opinion. Mr. Hadfield stated a most interesting fact, in that from a malleable iron casting he had obtained three per cent. of graphitic carbon; but we believe the casting showed all the physical qualities of having been well annealed. The result is of course not difficult to conceive, but the fact is none the less of interest. The action of silicon in regard to carbon in steel also occupied the attention of the meeting during this discussion, but we did not notice that any new facts were brought forward.

Mr. Bedson's paper on iron and steel wire was a very able contribution on a most interesting subject. The author is of the fourth generation of wire-makers, the business in which he is engaged having been handed down to him from his great-grandfather; whilst his father added some of the most important improvements to the machinery and process of wire manufacturing. The immense superiority of basic steel over that produced by the acid process was strongly insisted upon by the author; a fact which called forth some rather sharp remarks from Mr. James Riley, who protested against the acid Siemens steel being left unmentioned, as by far the greatest quantity of steel wire was manufactured from that metal. Mr. Bedson's paper was a long one; but if it had been even more extended, his audience would not have objected to it. For our own part, we should have been glad to have seen some mention made of the extraordinary tenacity in steel produced by drawing into wire.

The next paper taken was that of Mr. William Muirhead. Unfortunately this contribution was written in such a way that the author's meaning was somewhat obscure. From the wording of the paper we gathered that Mr. Muirhead would abolish the cogging process by which the ingot is broken down in rolls to manageable dimensions for rolling. This operation was originally performed by the steam hammer, and the cogging rolls were undoubtedly a great improvement, enabling work to be done with more expedition and greater cheapness. The author in his paper certainly advocated abandoning both hammering and cogging. In his paper he said, "Cogging, as it is at present carried on, with its consequent reheating, is a cumbersome, almost an ugly operation, and from the arguments I have endeavoured to adduce, an unnecessary one. How much smarter and cheaper it will be to take the ingots and roll them right off into plates, and I commend this to your earnest attention." Yet in the discussion which followed, Mr. Muirhead said that he did not in his system do without cogging. The point is one of considerable importance, and, Mr. Muirhead's position as the manager of an important steel-producing plant commands for him attention. If the same results can be got from the ingot without cogging and reheating, undoubtedly a great step in advance will have been taken; but the majority of steel-makers—perhaps we might say all, with the exception of Mr. Muirhead—think that cogging or hammering is a necessary though expensive process. Of course, if the author can show that he is right, and the rest of the steel world wrong, he will have performed a signal service to the industry. If we were the owners of steel works, however, we should prefer the experiments to be carried out by other manufacturers. It may be added that what is known as the direct process of rolling is not a new thing, and for Mr. Muirhead to succeed he will have to introduce some entirely fresh element into his procedure.

The last paper read at the meeting was Mr. Clarkson's contribution, in which he described his ore sampling machine. It would seem a small matter, at first glance, to sample ore, but it is by no means an easy thing to do. The variations in quality or composition are arbitrarily distributed, and it may easily be that a sample made up from portions from several different positions in the mass to be sampled, may not be a fair representation of the whole. Machines have been before used, by means of which small portions of a falling mass of ore may be abstracted at regular intervals. It would be difficult to describe this device without the aid of diagrams, but it may be stated that though they appear to work fairly and equitably at first sight, they are in reality partial in their selection. Mr. Clarkson has brought a trained mind to bear upon this subject, and has produced a really scientific instrument. The mass of ore is caused to fall in an annular stream, descending into a hopper, which is made to revolve at great speed. By a suitable mechanism small portions of the ore are abstracted at regular intervals, and from the fact that the falling mass takes the form of an annulus in place of a solid stream, the tendency of certain qualities to gather in the middle of the stream is obviated. A small-sized apparatus was shown in the theatre, and the author was able to practically demonstrate the accuracy with which it worked, so far as the exact percentage of the material abstracted from the whole was concerned. The demonstration, it may be said, was perfectly successful. The apparatus has another useful field in distribution of a mass into equal parts, so that by it a number of bottles or boxes can be filled without the tedious process of weighing being gone through, and yet each receptacle will have its due share of the material. The error of the ore separator is less than at present.

This was the last paper read at the meeting, which concluded with the usual votes of thanks.

THEORIES OF THE ORIGIN OF MOUNTAIN RANGES.

In his presidential address, delivered before the American Association for the Advancement of Science this year, Prof. Le Conte dealt with theories of mountain genesis—a subject which lies at the very foundation of theoretical geology. Want of space forbids us printing the address in full, but the most salient points are contained in the extracts from it that are here given.

Prof. Le Conte began by stating those fundamental features of the structure of mountain ranges on which every true theory of their origin must be founded. These features are: (1) Thickness of mountain sediments; (2) coarseness of mountain sediments; (3) folded structure of mountains; (4) cleavage structure; (5) granite or metamorphic axis; (6) asymmetric form. Another type of mountain, the main characteristics of which are not included under the above heads, are those only found in the Basin and Plateau regions, and therefore termed the Basin region type. In fact, "mountains may be divided into two types, viz. mountains formed by folding of strata, and mountains formed by tilting of crust-blocks. The structure of the one is anticlinal or *di*clinal, of the other, *mono*clinal. The Sierra probably belongs to both types. It was formed at the end of the Jurassic as a mountain of the first type, but the whole Sierra block was tilted up on its eastern side without folding at the end of the Tertiary, and it then became also a mountain of the second type. A complete theory must explain this type also; but since from the exceptional character it must be regarded as of subordinate importance, we shall be compelled to confine our discussion to mountains of the usual type."

Before going any further, however, Prof. Le Conte made a digression in order to clearly lay down what he meant by theory. After facts have been collected they must be explained, and the explanation, which merely gives the laws of the immediate phenomena in hand, is called the *Formal Theory*. The next step towards the perfection of knowledge consists in explaining the cause of these laws, and is termed the *Casual* or *Physical Theory*. The following is an illustration of this distinction:—

"All the phenomena of the drift are well explained by the former existence of an ice-sheet moving southward by laws of glacial motion, scoring, polishing, and depositing in its course. This is the formal theory. But still the question remains, What was the cause of the ice-sheet? Was it due to northern elevation, or to Aphelian winter concurring with great eccentricity of the earth's orbit? And if due to northern elevation, what was the cause of that elevation? A perfect theory must answer all these questions."

". . . . I wish to keep clear in the mind these two stages of theorising in the case of mountain origin. The formal theory is already well advanced toward a satisfactory condition; the physical theory is still in a very chaotic state. But these two kinds of theories have been often confounded with one another in the popular and even in the scientific mind, and the chaotic state of the latter has been carried over and credited to the former also; so that many seem to think that the whole subject of mountain origin is yet wholly in the air, and without any solid foundation."

Bearing in mind that "a true formal theory, keeping close to the immediate facts in hand, must pass gradually from necessary inferences from smaller groups to a wider theory which shall explain them all," Prof. Le Conte showed the inferences that could be made from the characteristic features of mountain structure, and he then grouped those inferences, and summed up his views as to the mode of mountain formation as follows:—

Summary Statement of the Formal Theory.

(1) "Mountain ranges, while in preparation for future birth, were marginal sea-bottoms receiving abundant sediment from an adjacent land-mass and slowly subsiding under the increasing weight. (2) They were at first formed and continued for a time to grow, by lateral pressure crushing and folding the strata together horizontally and swelling them up vertically along a certain line of easiest yielding. (3) That this line of easiest yielding is determined by the hydrothermal softening of the earth's crust along the line of thickest sedimentation. (4) That this line by softening becomes also the line of greatest metamorphism, and by yielding the line of greatest folding and greatest elevation. But (5) when the softening is very great, sometimes the harder lateral strata are jammed in under the crest, giving rise to fan-structure, in which case the most complex foldings may be near but not at the crest. Finally (6) the mountains thus formed will be asymmetric because the sedimentary cylinder-lenses from which they originated were asymmetric."

Several American examples illustrating these views were then given, and it was shown that eruptive phenomena, faults, mineral veins, earthquakes, and other minor phenomena associated with mountains are well explained by them. To quote Prof. Le Conte: "Leaving out the monoclinal type, which seems to belong to a different category, all the phenomena, major and minor, of structure and of occurrences, connected with mountains, are well explained by the theory of *lateral pressure* acting on lines of thick sediments accumulated on marginal sea-bottoms, and softened by invasion of interior heat. This view is therefore satisfactory as far as it goes, and brings order out of the chaos of mountain phenomena. It has successfully directed geological investigation in the past, and will continue to do so in the future.

"But there still remains the question, 'What is the cause of the lateral pressure?' The answer to this question constitutes the *physical theory*.

"Thus far I suppose there is little difference of opinion. I have only tried to put in clear condensed form what most geologists hold. But henceforward there are the most widely diverse views, and even the wildest speculations. But let us not imagine, on that account, that we have made no progress in the science of mountain origin. The formal theory already given is really for the geologist by far the most important part of the theory of mountain origin. For I insist that for the geologist, *formal* theories are usually more important than *physical* theories of geological phenomena. That slaty cleavage is the result of a mashing of strata by a force at right angles to the cleavage-planes, is of capital importance to the geologist, for it is a guide to all his investigations. To what property of matter this structure is due, is of less importance to him, though of prime importance to the physicist. That the phenomena of the drift is due to the former existence of a moving ice-sheet is the one thing most important to the geologist, guiding all his investigations. Whether this ice-sheet was caused by geographical or astronomical changes, is a question of wider but of less direct interest to him. So in the case of mountain ranges, the most important part of the theory is their origin by *lateral pressure* under the conditions given above. The *cause* of lateral pressure, though still of extreme interest, is certainly of less immediate importance in guiding investigations."

The Contraction Theory.

"The most obvious view of the cause of lateral pressure refers it to the *interior contraction of the earth.* This theory is so well known that I will give it only in very brief outline. It assumes that the earth was once an incandescent liquid, and has cooled and solidified to its present condition. At first it cooled most rapidly at the surface, and must have fissured by tension. But there would inevitably come a time when the surface, being substantially cool, and, moreover, receiving heat also from the sun, its temperature would be fixed, or nearly so, while the incandescent interior would be still cooling and contracting. Such has probably been the case ever since the commencement of the *recorded* history of the earth. The hot interior now cooling and contracting more rapidly than the cool crust, the latter, following down the ever-shrinking nucleus, would be thrust upon itself by lateral pressure with a force which is simply irresistible. If the crust were ten times, yea, one hundred times more rigid than it is, it must yield. It does yield along the lines of greatest weakness, *i.e.* along marginal sea-bottoms, as already explained. As a first attempt at a physical theory, it seems reasonable, and therefore until recently has been generally accepted."

Objections to the Contraction Theory.

"It is well known that American geologists have taken a very prominent part in the study of mountain structure and mountain origin; so much so, indeed, that the lateral pressure theory in the form given above and interior contraction as its cause, have sometimes been called the 'American theory.' It is also well known that my name, among others—especially Dana's—has been associated with this view. All I claim is to have put the whole subject, especially the formal theory, in a clearer light and more consistent form.[1] The formal theory I regard as a permanent acquisition. The contraction theory may not be so. It is natural, from my long association with it, that I should be reluctant to give it up. But I am sure that I am willing to do so if a better can be offered. We all dearly love our own intellectual children, especially if born of much labour and thought; but I am sure that I am willing, like Jephtha of old, to sacrifice, if need be, this my fairest daughter on the sacred altar of Truth. Objections have recently come thick and fast from many directions. Some of these I believe can be removed, but others perhaps cannot in the present condition of science, and may indeed eventually prove fatal. Time alone can show. I state briefly some of these objections."

(1) "Mathematical physicists assure us that on any reasonable premises of initial temperature and rate of cooling of the earth, the amount of lateral thrust produced by interior contraction would be wholly insufficient to account for the enormous foldings (*Cam. Phil. Trans.* vol. xii. Part 2, December, 1873). Let us admit—surely a large admission—that this is so. But this conclusion rests on the supposition that the whole cause of interior contraction is *cooling*. There may be other causes of contraction. If cooling be insufficient, our first duty is to look for other causes. Osmund Fisher has thrown out the suggestion (a suggestion, by the way, highly commended by Herschel) that the enormous quantity of water vapour ejected by volcanoes, and the probable cause of eruptions is; not meteoric in origin as generally supposed, but is original and constituent water occluded in the interior Magma. (*Cam. Phil Trans.* vol. xii. Part 2, February, 1875. "Physics of the Earth's Crust," p. 87.) Tschermak has connected this escape of constituent water from the earth with the gaseous explosions of the sun (*Geol. Mag.* vol. iv. p. 569, 1877). Is it not barely possible that we have in this an additional cause of contraction, more powerfully operative in early times, but still continuing? See the large quantity of water occluded in fused lavas to be 'spit out' in an act of solidification! But much still remains in volcanic glass which by refusion intumesces into lightest froth. Here, then, is a second probable cause of contraction. If these two be still insufficient, we must look for still other causes before rejecting the theory.

(2) "Again, Dutton (*Am. Jour.* vol. viii. p. 13, 1874; *Penn. Monthly*, May 1876) has shown that in a rigid earth it is impossible that the effects of interior contraction should be concentrated along certain lines so as to form mountain ranges, because this would require a shearing of the crust on the interior. The yielding would be evenly distributed everywhere, and therefore imperceptible anywhere. This is probably true, and therefore a valid objection in the case of an earth equally rigid in every part. But if there be a subcrust layer of liquid or semiliquid or viscous, or even more movable or more unstable matter, either universal or over large areas, as there are many reasons to think, then the objection falls to the ground. For in that case there would be no reason why the effects of general contraction should not be concentrated on weakest lines, as we have supposed.

(3) "But again, it has been objected that the lines of yielding to interior contraction ought not to run in definite directions for long distances, but irregularly in all directions. I believe we may find the answer to this objection in the principle of flow of solids under very slow heavy pressure. The flow of the solid earth, under pressure in many directions, might well be conceived as being deflected to the direction of least resistance, *i.e.* of easiest yielding.

(4) "But again, it will be objected that the amount of circumferential shortening necessary to produce the foldings of some mountains is simply incredible, for it would disarrange the stability of the rotation of the earth itself. According to Claypole, in the formation of the Appalachian range the circumference of the earth was shortened 88 miles, and in the formation of the Alps 72 miles. Now this would make a decrease of diameter of the earth of 28 miles in the one case, and 23 in the other. This would undoubtedly seriously quicken the rotation and shorten the day. This seems indeed startling at first. But when we remember that the tidal drag is all the time retarding the rotation and lengthening the day, and much more at one time than now, we should not shrink from acceptance of a counteracting cause hastening the rotation and shortening the day, and thus giving stability instead of destroying it. We must not imagine that there would be anything catastrophic in this readjustment of rotation. Mountains are not formed in a day, nor in a thousand years. It requires hundreds of thousands, or even millions of years—if physicists allow us so much.

"The objections thus far brought forward, though serious, are by no means unanswerable. But there is one brought forward very recently which we are not yet fully prepared to answer, and may possibly prove fatal. I refer of course to the level of no strain."

Level of No Strain.

"Until recently the interior contraction of the earth was considered only roughly and without analysis. It was seen that the

[1] "Theory of the Formation of the Great Features of the Earth's Surface," *Am. Journal*, vol. iv. p. 345 and 460, 1872; and also "Structure and Origin of Mountains," vol. xvi. p. 95, 1878.

surface was already cool, and its temperature fixed while the interior was still hot and cooling; and, therefore, that the exterior must be thrust upon itself and be crushed. But the phenomena are really far more complex than at first appears. It is necessary to distinguish between two kinds of contraction to which the interior layers are subjected, viz. radial and circumferential. If there were radial contraction only, then undoubtedly every concentric shell as it descended into smaller space would be crushed together laterally. But there is for all layers, except the surface, also a circumferential contraction, and this would have just the opposite effect, *i.e.* would tend to stretch instead of crush. Therefore, wherever the decrease of space by descent is greater than the circumferential contraction, there will be crush; and where the circumferential contraction is greater than the decrease of space by descent, there will be tension and tendency to crack. There would be no *real* cracking, only because incipient cracks would be mashed out, or rather prevented by superincumbent pressure. Where these two are equal to one another, there will be no strain of any kind. There is a certain depth at which this is the case; it is called the 'level of no strain.' To Mellard Reade is due the credit of first calling attention to this important principle."

After a diagrammatic representation of this principle, the president continued as follows:—

"Now laborious calculations have been made by Davison, Darwin, and Fisher to determine the depth of this level of no strain. All make it very superficial. Davison, taking an initial temperature of 7000° F. makes it five miles below the surface. Fisher, on the same data, only two miles, and with an initial temperature of 4000 only 0·7 of a mile. It is easy to see that if this be true the amount of lateral thrust must be small indeed.

"Now undoubtedly there is a true principle here which must not hereafter be neglected, but it is almost needless to say that these quantitative results are in the last degree uncertain. The calculations are of course based on certain premises. These are a uniform initial temperature of, say, 7000° F., a time of cooling, say, 100 or 200 millions of years, and a certain rate of cooling under assumed conditions. The depth of the level of no strain increases with the time, and is still going downward. In a word, in a question so complex, both mathematically and physically, and in which the data are so very uncertain, every cautious geologist, while freely admitting the soundness of the principle, will withhold assent to the conclusions. Huxley has reminded us that the mathematical mill, though a very good mill, cannot make wholesome flour without good wheat. It grinds indifferently whatever is fed to it. It has been known to grind peas ete now. It may be doing so again in this case. Let us wait.

"But besides withholding assent, and waiting for more light, I may add that these calculations, of course, go on the supposition that the whole contraction of the earth is due to loss of heat; but, as we have already said, it may be due also to loss of constituent water. This would put an entirely different aspect on the subject."

Alternative Physical Theories.

"I have given the objections to the contraction theory frankly and, I think, fairly. They are undoubtedly serious. Let us see what has been offered in its place."

I. Reade's Expansion Theories.

This, the most prominent among alternative theories, was first brought forward in Mr. Reade's book on "Origin of Mountain Ranges." Although I have carefully read all that Mr. Reade has written on this subject, I find it difficult to get a clear idea of his views. But as I understand it, it is in outline as follows: (1) Accumulation of sediments off shore, and isostatic subsidence of the same. (2) Rise of isogeotherms and heating of the whole mass of sediments and of the underlying crust in proportion to the thickness of the sediments. (3) Expansion of the whole mass in proportion to the rise of temperature. If there were no resistance this expansion would be in all directions (cubic expansion). (4) But since the containing earth will not yield to expansion laterally, this lateral expansion is satisfied by folding, and this in turn produces vertical upswelling. Thus the whole cubic expansion is converted into vertical expansion, which is therefore three times as great as the linear expansion in any one direction. (5) Elevation would of course anyhow be greatest along the line of thickest sediment; but this by itself would not be sufficient to produce a mountain. (6) But farther—and here the theory is more obscure—there is a concentration of the effects of expansion, along a comparatively narrow line of thickest sediments, by a flow of the hydrothermally plastic or even liquid mass beneath, toward this central line, and then upward through the parted starta, folding these back on either side, and appearing at the crest as the granitic or metamorphic axis. (7) In his latest utterances he seems to adopt the view of Reyer, viz. that the uplifted strata slide back down the slope, producing the enormous crumpling so often found, and exposing a wider area of granite axis. (8) From the same liquid mass which lifts the mountain come also the great fissure-eruptions and the volcanoes.

"Mr. Reade makes many experiments to determine the linear expansion of rocks, and he thinks that these experiments show that when cubic expansion is converted into vertical expansion, and this again concentrated along a line of one-fourth to one-fifth the whole breadth of the expanding mass, it would explain the elevation of the highest mountains. But still he seems uncertain if it be enough. In fact, he declares that if it were not for another factor yet unmentioned, he probably would never have brought forward the theory at all.

(9) "This factor is recurrency of the cause and accumulation of the effects. And here the previous obscurity becomes intensified. I have read and re-read this part without being able wholly to understand him. He seems to think that when expansion had produced elevation, the mountain thus formed would not come down again by cooling and contraction; but, on the contrary, would wedge up by normal faulting, and set in its elevated position. Afterward, by new accumulation of heat, another elevation and setting would take place, and the mountain grow higher, and so on indefinitely or until the store of heat is exhausted. Therefore, he characterises his theory as that of 'alternate expansion and contraction,' or, again, as that of 'cumulative recurrent expansion.' Such is a very brief, perhaps imperfect, but I hope fair outline of Reade's theory. It seems to me that there are fatal objections to it. These I now state."

Objections to the Theory.

(1) "The first objection is inadequacy to account for the enormous foldings of mountains, especially when there is no granite axis to fold back the strata. It is true that Mr. Reade makes comparison between his own and the contraction theory in this regard, and seems to show the much greater effectiveness of his own. This may be true if we accept his premises, and compare equal areas in the two cases. But the contraction theory draws from the whole circumference of the earth, and accumulates the effects on one line, while in Reade's theory the expansion is of course very local.

(2) "But the fatal objection is that brought forward by Davison. It is this: sedimentation cannot, of course, increase the sum of heat in the earth. Therefore the increased heat of the sediments by rise of isogeotherms must be taken from somewhere else. Is it taken from below? Then the radius below must contract as much as the sediments expand, and therefore there will be no elevation. Is it taken from the containing sides? Then the sides must lose as much as the sediments gain, and therefore must contract and make room for the lateral expansion, and therefore there would be no folding and no elevation. I do not see any escape from this objection.

"Thus it seems that Reade's theory cannot be accepted as a substitute. Is there any other?"

II. Dutton's Isostatic Theory.[1]

"Dutton's discussion of isostasy is admirable, but his application of it to the origin of mountains is weak. The outline is as follows:—

"Suppose a bold coast line, powerful erosion and abundant sedimentation. The coast rises by unloading, and the marginal sea-bottom sinks by loading. Now, if isostasy is perfect, there will be no tendency to mountain formation. But suppose a piling up of sediments—but on account of earth rigidity—without immediate compensatory sinking, and a cutting down of coast land without compensatory rising. Then there would be an isostatic slope towards the land. And the accumulated and softened sediments would slide landward, crumpling the strata and swelling them up into a mountain range.

"The fatal objection to this view is that complete isostasy is necessary to renew the conditions of continued sedimentation,

[1] Phil. Soc. of Washington, Bull. Vol. xi. pp. 51-64, 1889.

and therefore to make thick sediments, otherwise the sediments quickly rise to sea-level, and stop the process of sedimentation at that place. But it is precisely a want of complete isostasy which is necessary to make an isostatic slope landward. Dutton refers to Herschel as having suggested a similar cause of strata crumpling and slaty cleavage (*Phil. Mag.* vol. xii. p. 197, 1856); but the principles involved in the two cases are almost exactly opposite. Herschel supposes sediments to slide down steep natural slopes of sea-bottoms, and therefore sea-ward. Dutton supposed sediments to slide up natural, though down isostatic slopes, landward. Herschel's is a theory of strata-crumpling and slaty cleavage, Dutton's a theory of mountain formation.

"There has been no attempt to carry this idea of Dutton's to quantitative detail. It was probably thrown out as a suggestion in mere despair of any other explanation, for he had already repudiated the contractional theory. But the least reflection is sufficient to convince that such slight want of complete isostatic equilibrium as may sometimes occur, would be utterly inadequate to produce such effects."

III. Reyer's Gliding Theory.[1]

"Prof. Reyer has recently put forward certain views fortified by abundant experiments on plastic materials. His idea in brief seems to be this: strata are lifted and finally broken through by uprising fused or semi-fused matters, and these appear above as the granitic axis. As the axis rises, the strata are carried upward on its shoulders, until when the slope is sufficiently steep the strata slide downward, crumpling themselves into complex folds and exposing the granitic axis in width proportioned to the amount of sliding.

"No doubt there is much value in these experiments of Reyer, and possibly such gliding does indeed sometimes take place in mountain strata, and some foldings may be thus accounted for. But the great objections to this view are: (1) that there is no adequate cause given for the granitic uplift, and (2) that it utterly fails to account for the complex foldings of such mountains as the Appalachian and Coast Range, where there is no granite axis at all. Reade, indeed, holds that the Piedmont region is the granite axis of the Appalachian, and that the original strata of the eastern slope are now buried beneath the sea. But American geologists are unanimous in the belief that the shore line of the great interior Palæozoic Sea was but a little east of the Appalachian crest and the sea washed against land of Archæan rocks extending eastward from that line."

Conclusion.

"After this rapid discussion of alternative theories, in which we have found them all untenable, we return again to the contraction theory, not indeed with our old confidence, but with the conviction that it is even yet the best working hypothesis we have."

GEOGRAPHY AT THE BRITISH ASSOCIATION.

As in other sections, an absence of sensational papers, and an unusual abundance of good solid work, the outcome of study and research, were the characteristic features in Section E. The president's address was well adapted to his audience; the simplicity of its language, and the vivid descriptions of scenes in the Arctic Basin, with which it abounded, sustained the attention of every listener, and went over the head of none. Perhaps it was better calculated for the extension than the advancement of geographical science, but in many ways advance in geography depends on conditions different from those which determine advance in other sciences. Mr Seebohm rightly felt that to enforce principles familiar to professed geographers by a picturesque concrete example which no one could misunderstand was better than to record advances in specialised research, which could only appeal to the few geographers whose grasp of the subject equalled his own.

The section met on four days, and, including the presidential address, twenty-seven papers were read; a large number of members, in addition, took part in various discussions. A feature of the papers was the small number of mere records of travel, and the general striving after some kind of scientific elaboration of the data described. This was in some cases imperfectly done, but the imperfection was a consequence of the neglect of higher geographical education in this country, and the necessary beating out of new paths by independent workers, who, seeing the need for scientific treatment, are not always sure of the right methods to employ.

An inter-sectional discussion with Section C, on the limits between physical geography and geology, had been looked forward to with much interest, but proved somewhat disappointing. Few of the speakers addressed themselves to the subject announced, and in the extempore speeches it was evident that after a faint attempt to come to the point, there was a tendency to fall off on some familiar tack, and repeat irrelevant phrases often said before. In fact, there was no true discussion, as there was no distinct issue put forward.

Mr. Clements R. Markham, F.R.S., president of the Royal Geographical Society, commenced the proceedings by reading a paper, put together with consummate skill, in which he argued for the limit of human testimony as the line of demarcation between the domains of physical geography and geology. Thus he established a purely chronological division between phenomena of the same kind, which would fall to the province of one science or the other, according to the date of their manifestation. He concludes—

"Meanwhile, and until better instructed, I should define geology as the study of the condition of the earth and of the changes on its surface during the cycles of ages before the dawn of history; and I should define physical geography as a knowledge of the earth as it is, and of the changes which have taken place on its surface during historical times. These changes, derived from human testimony, explain to us the laws according to which similar changes are now taking place around us.

"The two sciences depend upon each other, and are very closely allied. The geologist finds the same phenomena in the rock formations of the past as the physical geographer discovers on the surface of the earth of the present. Both, for example, have the duty laid upon them of seeking out the agencies which rule in the processes of upheaval and depression. The fold, with its crest and trough, is common to both sciences; and geographers have rejoiced at the announcement of 'a wedding-ring of geology and geography uniting them at once and for ever in indissoluble union.'"

Mr. W. Topley, F.R.S., who followed, admitted the very close relations of geology and physical geography, but he devoted his attention to establishing the closeness of this relation by bringing forward numerous instances of the dependence of geographical features on geological structure, rather than to defining the limits of the two departments. His contention was that they merged the one into the other, and were not merely contiguous subjects separated by a discoverable line. Mr. E. G. Ravenstein supported Mr. Markham's chronological boundary, and summed up the conclusions of a racy speech in the statement that geology stands to physical geography in precisely the same relationship as history does to political geography. Prof. C. Lapworth, F.R.S., acknowledged the great difficulty of finding any satisfactory dividing line, contending that the geologist is in many ways absolutely dependent on the physical geographer, and the physical geographer in his turn absolutely dependent on the geologist, the physical geography of the present being indissolubly bound up with the physical geology of the past. Prof. Valentine Ball contended that the relation between geology and geography was similar to that between anatomy and art. Dr. R. D. Roberts, viewing geology as the history of the earth, argued that physical geography was merely the last chapter of that history. Dr. H. R. Mill suggested that a definition between the two departments of knowledge might be found rather in the aspect in which the phenomena of the earth were viewed than in the subject-matter or in chronological order. Physical geography being concerned with the present forms of the earth's surface borrowed from geology an explanation of the observed facts, taking results but not copying methods. Mr. H. Yule Oldham spoke of the unity of geography and of the importance of studying old travels in order to keep a record of recent physical changes. Prof. Bonney, F.R.S., characterised the discussion as waste of time and a search after the unattainable, for the words geography and geology contained in themselves all the definition that was required or could be found. Colonel Godwin-Austen and Mr. J. Y. Buchanan, F.R.S., made a few remarks; and Sir Archibald Geikie, who, by the consent of the presidents of Sections C and E, occupied the chair, summed up in a judicial manner. He

[1] Nature, vol. xlvi. p. 224, 1892, and vol. xlvii. p. 81, 1892.

sympathised with the desire to determine the best line of cleavage between the two contiguous portions of science, but had to acknowledge that any line which might be definitely formulated would, to a large extent, be artificial and arbitrary.

Several papers on physical geography were read to the Section, but they did not approach the geological border. Mr. J. Y. Buchanan communicated the preliminary results of some new experiments he has been conducting on the effect of land, water and ice on the temperature of the air, which promise, when completed, to extend our knowledge of climatology. Dr. H. R. Mill summarised the effect of different degrees of isolation from oceanic influences on the seasonal changes of temperature in the water and air of the Clyde Sea area, and Mr. H. N. Dickson communicated a brief preliminary note on the results of his recent trip in H.M.S. *Jackal* for the Fishery Board for Scotland, in the course of which he had examined the temperature and salinity of the water between the north of Scotland and the Färoe Islands. Dr. Schlichter submitted a piece of solid work in pure physical geography in the form of a series of ten vertical sections drawn across northern and central Africa from west to east. These sections exhibit graphically the relative heights of the continent as far as they have been ascertained, and by the blanks which occur where fixed points are wanting, they bring into sharp prominence the regions which are still practically unexplored.

Papers on the latest explorations were read by Mr. E. G. Ravenstein, who traced the opening up of Msiri's country by the Katanga Company's expeditions, and by Mr. E. Delmar Morgan, who communicated an admirable summary of recent exploration in Tibet. Mr. W. M. Conway described his work in the Karakoram mountains. Dr. H. R. Mill referred to the work which he and Mr. Heawood had carried out this year in the "unexplored England" of the lake-beds.

Most interesting amongst the explorational papers were the brief accounts, given by Mr. W. S. Bruce and Dr. C. M. Donald, of the cruise of the Dundee whalers *Balæna* and *Active* toward the Antarctic regions.

Mr. Bruce's communication may be summarised as follows:—

"After a boisterous passage of over a hundred days on the steam whaler *Balæna*, from Dundee, we met the first iceberg on December 16, 1892, in 59° 40′ S. 51° 17′ W. We continued on a more or less southerly course, passing to the east of Clarence Island. Danger Islets were sighted and passed on December 23, and on Christmas Eve we were in the position Ross occupied on New Year's Day, 1843. Until the middle of February we remained roughly between 62° S. and 64° 40′ S. and 52° and 57° W., the western limit being Terre Louis Philippe and Joinville's Land.

"All the land seen was entirely snowclad except on the steepest slopes, which were of black, apparently igneous, rocks. The few specimens of rocks obtained from the ice and from the stomachs of penguins bear this out; Prof. James Geikie finding olivine, basalt, basalt lava, and possibly gabbro among them. Rock fragments and earthy matter were seen on some of the bergs and ice. On January 12 we saw what *appeared to be* high mountainous land and glaciers stretching from about 54° 25′ S. 59° 10′ W. to about 65° 30′ S. 58° 00′ W. I believe this may have been the eastern coast of Graham's Land, which has not been seen before.

"The whole of this district south of 60° S. is strewn with bergs, and south of 62° S. they become very numerous. No entire day was recorded when bergs were not seen; as many as 65, all of great size, to say nothing of smaller ones, were counted on one day. The longest we met was about 30 miles long, one was about 10 miles long, and several from 1 to 4 miles in length. The highest the *Balæna* sighted could not have been over 250 feet high, and many were not over 70 to 80 feet high. All the bergs were tabular, or weather-worn varieties of that form. The base of the bergs is coloured brown by marine organisms.

"The pack ice is said not to be heavier than that of the north, and is similar in nature. It is frequently coloured brown by *Corythrum criophyllum*, a very abundant diatom. We first met pack ice on December 14, in 62° 20′ S. 52° 20′ W.; it was dense, and ran east and west. In January we met the pack edge running east and west in 64° 37′ S. from about 54° to 56° W.

"A few observations for the freezing and melting-point of ice were made, and some sea temperatures recorded. The lead was cast in the vicinity of Danger Islets, and some bottom samples obtained, the depth varying from 70 to over 300 fathoms.

"Periods of fine calm weather alternated with very severe gales, usually accompanied by fog and snow. The lowest air temperature recorded was 20·8° F. on February 17, and the highest 37·60° F. on January 15. December showed an average of 31·14° F., January 31·10° F., and February 29·65° F. The barometer never rose above 29·804 inches.

"No whale resembling *Balæna mysticetus*, *i.e.* the Bowhead or Greenland black whale, was seen; but many finbacks, some hunchbacks, bottlenoses, grampuses, and several kinds of seals, the hunting of which in default of whales was the object of the voyage."

Messrs. Bruce and Donald showed a very creditable collection of observations, but the main outcome of their papers was a demonstration of the immense value of the results which would accrue from a purely scientific expedition to Antarctic waters. Mr. Bruce announced that he was prepared to spend a year, with an assistant who had volunteered to accompany him, on South Georgia or on Grahamsland, if he could be landed there, and to undertake systematic scientific work during that time, if his passage-money and maintenance were paid for. Mr. J. S. Keltie, Mr. H. O. Forbes, Mr. Coles, Dr. H. R. Mill, Mr. Ravenstein, Sir George Bowen, Mr. G. J. Symons, F.R.S., Colonel Fred. Bailey, and others, pointed out the immense importance of Antarctic exploration to geography, geology, meteorology, and other sciences, and warmly commended Mr. Bruce's resolution to conduct a series of preliminary observations. The audience, which included Dr. Burdon Sanderson, the president of the Association, received the papers and discussion with enthusiasm, and a subscription list was started in order to supplement any grants which might be obtained from learned societies to provide a scientific outfit for Mr. Bruce and his assistant. A committee of Section E was charged with the necessary arrangements, with Mr. Clements R. Markham as chairman, and Dr. H. R. Mill as secretary. The Committee of Recommendations voted a grant of £50 for the purposes of this committee. The question of Antarctic exploration was supported by a letter from Sir Erasmus Ommaney, enclosing an appeal from the Australian Antarctic Explorations Committee, suggesting that the British Association should take steps to induce the Australian Government to subsidise southern sealing voyages. A collection of water-colour sketches, by Mr. W. G. Burn-Murdoch, of Edinburgh, who was a passenger on the *Balæna*, illustrating the scenery and incidents of the voyage, was arranged round the meeting room, and attracted a great deal of attention. The collection has already been shown in Dundee, and arrangements have been made for exhibiting it in London in the map room of the Royal Geographical Society. Unfortunately, there were no press representatives in the meeting-room during the greater part of the Antarctic discussion, and it has consequently almost entirely escaped attention in the daily papers.

Papers on special parts of the world, summarising results of travellers and geographers, were read by Mrs. Lilly Grove, on the Chiloe Islands; by Mr. Howard Reid, on the relation of Lake Tanganyika to the Congo; and by Mr. Cop Whitehouse, on the Lower Nile Valley, with reference to the various delineations of it in Ptolemaic and later maps. Mr. E. Heawood read a paper recounting his experiences in the Bengal Duars, with special reference to the settlement of Santal colonists in that region. Mr. Heawood said:—

"The term 'Duars' is applied to a tract of country lying along the foot of the Himalayas of Bhután, and including the 'doors' or passes into that country. The first ranges here rise like a wall, wooded to their summits, from an undulating plain of slight elevation, which embraces a strip of forest-clad 'Terai' and a more open country further south. Over a great part savannahs of gigantic grass alternate with patches of forest, sál on the higher and lighter soils, and mixed forest fringing the streams. The grass is burnt down annually, and the trees with which it is dotted are usually quick growing and shed their leaves annually, and are thus less affected by the burnings. The tiger, leopard, bear, elephant, rhinoceros, buffalo, bison (so-called), pig, and several kinds of deer inhabit the jungles. The peacock, jungle-fowl, florikan, parrots, and a handsome pigeon are the most prominent birds. The rainfall is very great, and the climate unhealthy, though this improves with clearing. The tract is sparsely inhabited, except in the southern and newly-settled parts, by Mechs, a tribe of Mongolian affinities who can thrive in spite of the malaria. They are of wandering habits, cultivating by burning patches of jungle, and moving on to new spots after a few years. Much of the land is very fertile, and well suited for both early and late rice crops. Channels, often of great length, are dug by the Mechs from the numerous streams for the irrigation of the late rice crops, though the tendency of the rivers to deepen their beds in the friable soil is a difficulty to more permanent settlers. The climate and the exposure to raids from Bhután have keep the country in a backward state. It became British territory as a result of the war of 1864. Much land has since then been settled and tea-gardens opened, especially in the western part; while within the last three years a large tract of jungle has been provisionally set apart by Government—at the instance of the Rev. A. J. Shields, C.M.S. missionary to the Santals, warmly supported by Mr. D. Sunder, settlement officer at Jalpiguri—for settlement by Santals, who in their hill country south of the Ganges are often unable to obtain sufficient land for cultivation. Forty families were taken up in 1891, the author assisting in their settlement, and still larger numbers have followed since. Although the partial failure of the rains in the first season caused unforeseen difficulties at first, these, it is hoped, are now in a fair way to be overcome. It should be mentioned that a similar experiment has been tried with success in Assam by a Norwegian mission."

Captain Williams, R.A., gave a popular address on the people of Uganda; Mr. Herbert Ward sent a short paper on the people of the Congo Basin; and Dr. R. W. Felkin submitted a new scheme for a map of the distribution of diseases in Africa. The Rev. C. H. Robinson gave an interesting account of the adventures of a Hausa pilgrim who passed through Khartum on the way to Mecca immediately after the capture of the town by the Mahdi, and gave a new version of the story of General Gordon's death. Mr. E. G. Ravenstein read a brief report of the Committee on African Climatology, which is engaged in accumulating meteorological data from the tropical parts of the colony.

Many of the communications were illustrated by the lantern, and the last paper read was on a system of geographical teaching in which the lantern is adapted for general use in schools, by Mr. B. Bentham Dickenson, of Rugby. A small association has been formed in order to promote this object.

The meetings of the Section were never attended by a larger average number than this year, and on the whole the scientific value of the papers has seldom been greater.

MECHANICS AT THE BRITISH ASSOCIATION.

IN Section G, that devoted to mechanical science, at the recent Nottingham British Association meeting, there were fewer papers read than usual. This, however, was a distinct advantage, for this section has generally suffered from an overabundance of matter. It is far more satisfactory to have a few good papers well discussed than a multitude of mediocre or inferior contributions, which only weary the audience, and lead to no good result. The section held its meetings in the Engineering Lecture Theatre, at University College, and the first sitting took place on Thursday, September 14, according to precedent. The president this year was Mr. Jeremiah Head, whose address we reprinted on September 21. The first paper taken was a contribution by Mr. Beaumont, entitled the "Automatic Balance of Reciprocating Mechanism," and referred to a method of utilising the vibration caused by a revolving weight for working sieves. In the discussion which followed, the opinion was expressed that the device might find a useful place in other applications than that for which it was originally intended. The rest of Monday's sitting was taken up by a description of lace machinery and hosiery machinery. Although the subject is one of considerable interest, it would be impossible to give any adequate idea of the proceedings without the numerous diagrams and lantern slides which were used by the author of the paper. Several of the most interesting machines described were shown at work in an adjoining room, and their action was explained by Mr. W. Robinson, the Professor of Engineering at University College, Nottingham.

On Friday, the 15th inst., two reports were down for reading; the first that of the committee on the dryness of steam in boiler trials, in regard to which Prof. Unwin stated that practically nothing had been done during the past year, and therefore there was no report to present. It was hoped, however, that by following certain lines of investigation which had been suggested by some American experimentalists, that good results might be arrived at, and it was hoped that a satisfactory report would be prepared for the next meeting. The report of the committee on Graphic Methods was a contrast to Prof. Unwin's statement; it being of an exceedingly voluminous character. This is the second long report that has been presented by the committee. It would be quite impossible to deal with the subject in an account of the proceedings such as we are able to give, which must necessarily be brief, and as the report will be printed in full, in common with all reports of committees, in the Proceedings, we will refer our readers to the volume when it is issued, for information on this really important subject. It is fair, however, to notice the immense amount of good and sound work that Prof. H. S. Hele Shaw has done, as secretary, in preparing the reports of this committee.

Two papers on the disposal of refuse followed; one by Mr. C. C. Keep, and the second by Mr. William Warner. In these various descriptions of destructors which had been placed upon the engineering market were described. Both authors are, we believe, members of firms which manufacture and sell apparatus of this description, and trade interests were not altogether lost to sight. The subject of refuse destruction is one of great importance, but it requires, in the interests of sanitary science, to be handled in a somewhat different manner to that pursued by the section in the reading and discussion of the papers. Mr. Frank Ashwell next read a paper on "Warming and Ventilating," in the course of which he discussed the merits of the plenum system, as against the method of ventilation by partial vacuum. He had not much difficulty in establishing the claims of the former; the chief advantage, of course, being that with a plenum inside the building any leakage there may be at doors, windows, &c. does not admit draught; the air for ventilation always coming in through the proper entrance, where it may be warmed, filtered, and, if necessary, moistened. Watchmaking by machinery next occupied the attention of the section, Mr. T. P. Hewitt, of Prescot, reading an interesting paper on the subject. As was stated by a speaker during the discussion which followed, watchmaking in England has been lately at a very low ebb. For many years it has had to meet the competition of cheap labour in Switzerland, but the most fatal blow to the system was struck by the introduction of the factory system for the manufacture of watches in America. By the use of machine tools and labour-saving appliances the Americans have been able to produce excellent timekeeping watches at a very moderate cost; for the industry is one specially suited to the genius of the American mechanic, whose inventive faculties are proverbial. So serious a blow has thus been inflicted on the English watchmaking industry that its operatives were brought to the greatest distress. Prescot, in Lancashire, is a very ancient centre of watchmaking, that is, so far as the movement of the watch is concerned, and many of the best English watches have Prescot works. It is in this town that an endeavour is being made to revive the English watchmaking industry, but on entirely new lines. A large factory has been built, and the most improved appliances introduced. These, of course, are largely American in origin, but it is satisfactory to know that the beautiful machine tools, such as used by the Waltham and Elgin Watch Companies, can now be made in England, and are equal to the productions of the United States. Several examples of these machines were exhibited during the reading of the paper.

Mr. Ross, of Glasgow, next described a pneumatic caulking and chipping tool. This is a hand-tool, working, as its name would imply, by compressed air, or steam may be used. It will make over 10,000 strokes per minute, and consists essentially of a small cylinder and loose piston, which works on to the caulking or chipping chisel. The only thing the operator has to do, therefore, is to guide the tool, and the enormous rapidity of the strokes enables the finest work to be done, either in caulking a metal seam or in chipping down a metallic surface. Some very beautiful specimens of work were shown at the meeting, and the instrument itself was exhibited.

It is the custom of Section G to devote Monday of the Association meeting to electrical science, and the first paper taken on the 16th was a contribution by Mr. Gisbert Kapp, entitled "Relative Cost of Conductors with Different Systems of Electrical Power Transmission." This was a most useful paper, and a good example of the form contributions on electrical subjects should take in Section G, where, it must be remembered electrical engineering, and not physics, should be treated upon. The author said that until recently, electrical machines for the transmission of power were of the continuous current type, but lately alternate current apparatus had come into use, chiefly because the power could be carried to greater distances with a moderate cost of conductors. The reason for this was that with continuous current plant the voltage is limited by the difficulty of insulating the generating machinery. With alternate current there is no necessity of high insulation of generator or motor, but only of the transformers, which can be easily insulated by the use of oil or other means. The author dealt with five systems of transmission.

(1) Single phase alternating current transmission by two wires.
(2) Double " " " " " four "
(3) " " " " " " three "
(4) Three " " " " " three "
(5) Continuous current with transmission by two wires.

We have not space to follow Mr. Kapp's ingenious reasoning, but will briefly give his conclusions. If all systems were put on the same footing as regards efficiency and safety of insulation, the following results would be obtained. If, for the transmission of a certain power over a given distance by continuous current, 100 tons of copper were required for the line, then the single phase alternating and the two phase four wire system would require 200 tons. The two phase three wire system would require 290 tons, and the three phase three wire system only 150 tons; therefore, so far as the line might be concerned, there would be a distinct advantage in the employment of the three phase system.

A paper by Mr. A. B. Snell, "On Water Power as a Source of Electricity," was next read. The subject is not one of such great practical importance in England as in more mountainous countries. Our rivers are small, and in comparatively few cases is there sufficient head to make the utilisation of them profitable with such a form of water motors as have yet been introduced. Mr. Beaumont described a variable power gear for electrical locomotives which he had devised. The object of the gear is to give increased power for the motor when starting the train. By its use the designer hoped that electric motors might be made of very much smaller size. A point of interest raised during the discussion was the advisability of using epicycloidal gear, it being the opinion of Prof. Hele Shaw and others who had worked with this gear that it was not suitable for heavy loads. Mr. W. B. Sayers read an interesting and valuable paper, in which he described a form of self-exciting armature and compensator for loss of pressure, which he had devised. The invention is one of considerable importance, the object being to obtain sparkless commutation. The device, however, is not quite new, it having been previously described, and doubtless is known to the majority of our electrical readers. Monday's proceedings closed with a paper by Mr. E. Payne, on "Electrical Conductors."

Tuesday, September 19, was the last day on which Section G met, and the proceedings opened with a paper by Mr. O. T. Olson, on "Flashing Lights for Marine Purposes." The author proposed that each important navigational light in the world should have a distinctive number which it should continuously flash at night, so that there might be no danger of any particular light being mistaken by the mariner for another. During fog the signals were to be conveyed by gun-cotton explosion. Probably Mr. Olson's suggested signals are somewhat too complicated, although possibly as simple as could be practically arranged were every light given a separate number. Nevertheless, something might be done towards systematising the signals given by various lights in certain geographical sections.

Mr. William S. Lockhart gave an interesting description of an automatic gem separator which he had devised. The apparatus acts by means of the difference in specific gravity between the gems and the gravel, quartz, &c., in which they are found. A stream of water flowing at a uniform velocity is directed upwards through an annular chamber. The material to be separated is fed in through a hopper at the top of the apparatus, and falls into the annular chamber. The velocity of the stream is so regulated that the lighter and more worthless substances are carried with it, whilst the heavier gems descend into a receptacle at the bottom of the machine. One of the separators was shown at work in the Section, water being laid on for the purpose, and some diamonds were actually separated from the pebble and quartz with which they were mixed. There are, it is hardly necessary to say, many points in detail which require careful consideration in working out before such a machine as this is brought to the perfection of practical working. Mr. Lockhart appears to have been very successful in overcoming the difficulties of the problem he had to solve in designing the machine.

A paper by Mr. Walker, "On Ventilating Fans," was read, and the proceedings in this Section closed by Prof. Robinson describing the Wicksteed testing machine, which had been erected in the engineering laboratory of the college. The members of the Section were able to see this machine in action during the afternoon. In most respects it does not differ from the ordinary type of Wicksteed testing machine, but there is a clever gear for shifting the poise. This was operated by hydraulic power by means of wire rope. The device is undoubtedly an improvement on the old gear, both in rapidity of action and absence of noise. There is a neat parallel adjustment for preventing the pulley of the rope influencing the result of the test.

The proceedings in Section G were brought to a conclusion by the usual vote of thanks to the sectional president, Mr. Jeremiah Head.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

AFTER the President's address on Thursday, Mrs. Lilly Grove read a paper on the ethnographic aspect of dancing. Dancing corresponds to a universal primitive instinct in man. At all periods there were three kinds of dances: (1) the imaginative or poetic; (2) the descriptive; (3) the religious. This last is most important, and may be called the fountain of the other kinds. Religious dances can be divided into two classes: (*a*) dances directly in honour of the deity; (*b*) dances intended to propitiate the deity. A strange feature is the fact that so many dances are performed in a circle. War-dances are of two orders, either as a preparation for war, or as a rejoicing after triumph. The Corroboree illustrates the former aspect. Excellence in dancing among savages is obtained by very simple means: anyone who makes a mistake is killed.

Prof. Windle read a paper on anthropometric work in schools. It appears from answers to a circular sent to the head-masters of one hundred of the largest schools in the United Kingdom, that some form of measurement is or has been carried on in twenty-five schools, but that the methods adopted differ considerably. The author suggested that an endeavour should be made to encourage and systematise such work.

Dr. W. Wilberforce Smith read a paper on anthropometric weighing; and the following reports were also presented to the section: Report of the Anthropometric Laboratory Committee, and Report of the Physical Deviations Committee.

On Friday, the committee appointed to make an ethnographical survey of the United Kingdom presented their first report. Prof. Hans Hildebrand then read an important paper on Anglo-Saxon remains and coeval relics from Scandinavia. The question proposed was to determine the relations which existed between the civilisation of Scandinavia and that of England during the period between the arrival of the Angles and the Saxons on the English coast, and the time of their conversion to Christianity; roughly, that was from the middle of the fifth to the middle of the seventh century of our era. These limits were not exactly determinable, because both the Anglo-Saxon immigration and the spread of Christianity among the newcomers were not the work of a few years only, and progressed with very different rapidity in different parts of the country. During this period Sweden had no chronological record, and Christianity had no hold on that country until the eleventh century. The criterions of date, therefore, on the Scandinavian side were of purely archæological character. There were a few instances of Roman and Byzantine coins found associated with Scandinavian antiquities, and as these could hardly have found their way northward before the downfall of the Hunic Empire in Central Europe, they gave some indication of the date of the objects with which they were lost or interred. In England similar date evidence occurred, but was vitiated by the fact that the coins had often been long in circulation before they were buried. The practice of burial also, while it entirely superseded cremation when Christianity became predominant, appeared to have coexisted with the older method during the later Pagan period, and could not be taken as affording an accurate criterion of age.

And there was the further difficulty in comparing English and

Scandinavian objects, that in England the Teutonic peoples found the British and Romano-British culture already existing on their arrival, while there was no parallel influence to modify the style of Scandinavian art. The author discussed the Scandinavian types of sword and spear, which presented both remarkable likenesses and differences when compared with those which gave their name to the Saxons (sword-men) and the Angles (spear-men). The boar-crest on the helmet also appeared to be a point of similarity. Numerous examples were adduced to show how designs borrowed from existing art were modified to suit Teutonic taste in the English series, which herein came nearer to the French and Belgian than to the Scandinavian. As illustrations of the development of style, the ornamental fibulæ or brooches were of especial importance, and a number of types were instanced which showed the fundamental likeness of Teutonic taste on both sides of the North Sea, combined with differences in detail. Summing up his results, Prof. Hildebrand concluded that a common Teutonic taste was the source of the art styles both of Scandinavia and of Saxon England; that the Scandinavian and Anglo-Saxon races were of closely allied Teutonic descent, but that in the incessant movements characteristic of that stock, the two branches were separated from one another and developed independently; that the Kentish Jutes and the Saxons of England came not from Scandinavia, but from Germany; but that the case was not clear with regard to the Angles, who might possibly not be of German origin, but may have been settled at one time in the south-west corner of Scandinavia.

In a paper on the "Origin and Development of Early Christian Art," Mr. J. Romilly Allen traced the various decorative elements found in early Christian art in Grea Britain to their source, and showed in what way the native styles of art existing in this country at the time of the introduction of Christianity (*circa* A.D. 450) were influenced, first by the Italo-Byzantine art, which came in with the importation of the illuminated manuscripts used in the services of the church, and subsequently by the coming in contact of the Anglo-Saxon and Scandinavian conquering races with the Celtic and other populations already inhabiting the British Isles.

The following papers were also read:—Note on an implement of hafted bone, with tooth of hippopotamus inserted, from Calf Hole, near Grassington, by the Rev. E. Jones; the prehistoric evolution of theories of punishment, revenge, and atonement, by G. Hartwell Jones; four as a sacred number, by Miss A. W. Buckland.

On Saturday the following papers were read:—On ancient metal implements from Egypt and Lachish, by Dr. J. H. Gladstone, F.R.S.; notes on flint saws and sickles, by Dr. R. Munro; prehistoric remains in Crete, by J. L. Myres; funeral rites and ceremonies among the Tshinyaï or Tshinyangwe, by Lionel Decle; the Arungo and Marombo ceremonies among the Tshinyangwe, by Lionel Decle; the Ma-Goa, by Lionel Decle.

On Monday, a paper by Mr. Herbert Ward was read, entitled "Ethnographical Notes on the Congo Tribes." In it the author gave a sketch of all the salient features of native life in the Congo region, the subjects treated at greatest length being those relating to superstition and general customs. In the description of the "N'Kimba" ceremony of the Lower Congo natives, the motive for this remarkable "secret society" was, for the first time, explained.

Dr. Crochley Clapham read a paper on "The Mad Head," in which he said that the older phrenology of Gall had been superseded by Ferrier's cerebral localisation. He then gave some results of his examination of nearly 4000 insane heads drawn from eight asylums in the north of England and the south of Scotland, and compared with a number of sane heads. Insane heads he found to show a larger average size than sane ones, though insane brains were smaller. His standard of comparison was by a cranial index which he obtains by adding together the measurements of the whole circumference and the antero-posterior and transverse arches of the head. Of these measurements that of the transverse arch was the only one smaller in the insane, and was, in fact, their weak point. The cranial index he found further useful as, when expressed in inches, it showed about the weight of the normal contained brain in ounces. The frontal segment of the head circumference bore a larger proportion to the whole circumference in the insane than in the sane, and this, taken with the fact that the frontal lobes in idiots and imbeciles weigh more in proportion to the whole encephalon than in the total insane class, and the fact that the typical insane head was cuneiform with the greatest transverse diameter anterior to the central point of the head, seemed to discredit the "noble forehead," and to point out the occipital lobes as the seat of intelligence. This view was supported by facts of brain development and comparative cerebral anatomy, as well as by the flat occiput of idiots and the cerebellum of the bushman projecting beyond the occipital lobes.

In a paper on pin-wells and rag-bushes, Mr. E. Sidney Hartland suggested that the object of the usages was union with the divinity, to be achieved by the perpetual contact with the god of some article identified with the worshipper.

The following communications were also received:—Report of the Abyssinian Committee. On the external characters of the Abyssinians examined by Mr. Bent, by Dr. J. G. Garson; on the Dards and Siah-Posh Kafirs, by Dr. J. Beddoe and Dr. Leitner; the Primitive Americans, by Miss J. M. Welch; the Indians of the Mackenzie and Yukon Rivers, Canada, by the Rt. Rev. Dr. Bompas, Bishop of Selkirk; the Australian natives, by Miss J. A. Fowler; on a modification of the Australian aboriginal weapon termed the Leonile, Langeel, Bendi, or Buccan, by R. Etheridge, jun.; on an unusual form of rush-basket from the northern territory of South Australia, by R. Etheridge, jun.

On Tuesday, Mr. Francis Galton read some official letters just received by him from Surgeon Lieut.-Colonel Hendley, of Jeypore, who had memorialised the authorities in India in favour of affixing to the nominal roll of recruits an impression in ink of the fore, middle, and ring fingers of each recruit. In reply, the Commander-in-Chief "approved of the proposal to employ prints of finger-tips as marks for identification, as they are so extremely easy to make, and so useful in guarding against personation." Surgeon Lieut.-Colonel Hendley has had considerable experience in taking such imprints, having already sent to Mr. Galton those of the digits of nearly 1000 persons, most of whom were prisoners in the gaol of Jeypore.

Dr. Munro read a paper on the structure of lake-dwellings, in which he described the various methods adopted by the lake-dwellers in the construction of the understructures and platforms on which their huts had been placed. In conclusion, Dr. Munro gave a description of an important discovery recently made in Argyllshire. This was a crannog showing foundations of a circular house thirty-two feet in diameter, and divided into two compartments, one of which contained a hearth and the remains of a doorway.

Mr. Arthur Bulleid then read a paper on a British village of marsh dwellings. This village, discovered by the author in March, 1892, is situated a little more than a mile north of the town of Glastonbury, in the upper part of one of the moorland levels of central Somerset, found to the south of the Mendip Hills. There is little on the surface to indicate the site of a village, but on careful inspection between sixty and seventy low circular mounds may be seen, varying from 15 to 35 feet in diameter, and from 6 in. to 2 ft. 6 in. high at the centre. These form the foundations or floors of separate dwellings, which are constructed in the following way:—On the surface of the peat is a layer or platform of timber and brushwood, kept in place by numerous small piles at the margin. On this a layer of clay is placed, slightly raised at the centre, where the remains of a hearth are generally found. The dwelling itself was composed of timber filled in with wattle and daub. Not only have the wall-posts been found *in situ*, but also the entrance threshold and doorstep. Among other things that have been discovered is a boat 17 ft. long, quantities of wheel and hand-made pottery, sling stones, and bones of animals, and a great number of objects of bronze and iron, horn, bone, and stone, such as fibulæ and rings, knives, saws, and weapons, combs, needles, pottery stamps, and querns.

In a paper on the place of the lake dwellings at Glastonbury in British Archæology, Prof. Boyd Dawkins referred to the existence of crucibles to show that smelting had been carried on, and reasoned that the time of the occupation of the place was pre-Roman.

The following communications were also received:—On the excavation of the stone circle of "Lag ny Boiragh," on the Meayll Hill, Isle of Man, by Prof. W. A. Herdman, F.R.S., and P. M. C. Kermode; early uses of flint in polishing, by H. Stopes; palæolithic anchors, anvils, hammers, &c., by H. Stopes; Report of the Uniformity in Spelling Committee; Report of the North-Western Tribes of Canada Committee.

THE EVOLUTION OF COLOUR IN THE GENUS MEGASCOPS.

THE *American Naturalist* of June and July contains an article by Mr. E. M. Hasbrouck on "Evolution and Dichromatism in the Genus Megascops," in which he deals with the distribution of the genus in North America in relation to the colour of its plumage. The discussion leads to the following conclusions:—

"The red phase is confined mainly to *Megascops asio* (speaking of it as a whole), which, on its northern border, merges into the grey phase; the southern grey belt incompasses *floridanus*, while in eastern Texas the few red specimens of *mecallii* that are known have been taken from the extreme north-eastern portion of its range, which is influenced both by humidity and temperature. Again this distribution of colour corresponds very closely to the life areas—the grey phase of the Florida form in the south occupying a major portion of the Austroriparian; the red phase of *asio* proper conforming very closely to even the outlines of the Carolinian, while the grey phase is equally identical with the Alleghanian.

"It is worthy of note that the grey phase of *Megascops asio* is boreal in its affinities, and that where a grey phase of *asio* is found that is not boreal, it is recognised as a sub-species.

"Now if *floridanus* (grey) is separable from *asio* just north of it (red), it seems highly probable that *asio* (red) will some day be separated from the grey phase on the north. It has been shown that as regards the two phases of *asio*, certain areas are inhabited exclusively by reds, certain ones exclusively by greys, while still others are inhabited by a mixture of the two, and that three forms (*floridanus* and two colour phases of *asio* proper) inhabit, as a whole, entirely distinct areas. No one will deny that all of the forms of *Megascops* are descended from a common ancestor, and if through climatic or environmental conditions they have become sub-specifically differentiated in various localities, I see no reason to doubt that in like manner, under the influence of humidity, temperature, acquired character, and forest area, which will be felt for countless generations to come, that the species now known as *Megascops asio* will one day be separated into species and sub-species—the former represented by the original grey, and the latter by the more modern red."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Medical Session began on Monday in the schools attached to the London and provincial hospitals. Dr. W. Pasteur delivered the introductory address at Middlesex Hospital, and Mr. Thomas Holmes at St. George's Hospital. The subject of Mr. Holmes's discourse was the life and works of John Hunter, being the centenary celebration of Hunter's death within the walls of the hospital. The address at St. Mary's Hospital was delivered by Mr. J. Ernest Lane, and at the London School of Medicine for Women by Miss Helen Webb. Biology and ethics formed the subject of the opening address delivered by Sir James Crichton Browne at the Sheffield School of Medicine.

MR. WALTER GARSTANG, of the Plymouth Marine Biological Laboratory, has been elected to a Research Fellowship by Lincoln College, Oxford.

THE first entrance scholarship to St. Thomas's Hospital Medical School, of the value of £150, has been awarded to Mr. Robert Wynn Charles Pierce, and the second, of the value of £60, to Mr. Harry Edward Hewitt.

THE Entrance Scholarship, of the value of 120 guineas, to Charing Cross Hospital Medical School has been awarded to Mr. Harold A. T. Fairbank, and that of the value of 60 guineas to Mr. Stanley W. R. Colyer.

THE following entrance scholarships to Guy's Hospital have been awarded in science. First, of the value of £150, to Philip Turner, University College, London; second, value £60, to George Ernest Richmond, Owens College.

THE Balfour Studentship, of the nett annual value of £200, will be vacant on October 18. From the regulations sanctioned by the Senate of the University of Cambridge, it appears that the studentship is not awarded upon the result of a competitive examination, and the student need not be a member of the University. The holder of the studentship must devote himself, however, to original biological inquiry, and must not follow any business or profession, or engage in any educational or other work, which, in the opinion of those charged with the administration of the Balfour Memorial Fund, would interfere with his original inquiries.

MR. W. TOWNSEND PORTER has investigated the relation between physical development and success in school life, his data for discussion being obtained from 33,500 boys and girls in the public schools of St. Louis (Transactions of the Academy of Science of St. Louis, vol. vi. No. 7). The weight of a child can usually be taken as a trustworthy index of physical development, and, comparing it with standards of intelligence, it appears that precocious children are heavier, and dull children lighter than the average child of the same age. Not only is this the case, but precocious children are taller, have larger chests, and wider heads than dull children. An examination has also been made of the relationship between precocity and rate of growth, or yearly increase in size, and the results indicate that the difference in weight between dull and precocious boys increases as they grow older. The conclusions arrived at are based upon means and averages, and may not be applicable to individuals. However, one deduction of considerable importance is made. It is that no child whose weight is below the average of its age should be permitted to enter a school standard beyond the average of its age, except after such a physical examination as shall make it probable that the child's strength shall be equal to the strain.

SCIENTIFIC SERIALS.

THE *Meteorologische Zeitschrift* for July contains an account of observations taken at the Hawaiian Islands, communicated by Dr. Marcuse, of the Berlin Observatory, who for some time visited Honolulu for astronomical investigations. The position of those islands, near the northern limit of the tropical zone, is very important from a meteorological point of view, and the Hawaiian Government have for some years past established a regular service under Mr. C. J. Lyons, who publishes a monthly meteorological summary. The principal station is at Punahou (Oahu), a little to the north-east of Honolulu, on which island there are also sixteen other stations, also twenty-three stations on the island Hawaii, and fourteen on the other islands, making altogether a total of fifty-four, two of which are 4100 feet above sea-level. The oldest temperature observations date from the time of the first American mission in 1821, and with some interruptions have been continued to the present time. From the more recent observations the mean annual temperature is 74°·1. During the last ten years the lowest temperature was 54°·0, and the highest 89°·1; the greatest daily variation being 23°. The warmest month is August, mean temperature 78°·1, and the coldest, January, mean 69°·8. Barometric pressure is very regular, the yearly period amounting to about ·07 inch, and the daily period to ·06 inch. The larger oscillations occur only when the almost regular northerly trade winds, which blow on an average for 258 days in the year, are replaced by southerly winds. The rainfall differs considerably in different parts of the islands; at Honolulu the mean of thirteen years' observations is 30·6 inches. The largest amount falls between November and February; the dryest month is June, with about one inch.

August.—"Die neue Anemometer-und Temperatur-Station auf dem Obir-Gipfel," by J. Hann.—On the dynamics of the atmosphere, by M. Möller. This is a continuation of a series of valuable papers on the physics of the atmosphere. The present article deals chiefly with the behaviour of cyclones and anticyclones, and with the vertical distribution of temperature and aqueous vapour.

THE *Botanical Gazette* for August has an article on cell-union in herbaceous grafting, by Mr. John S. Wright, in which the remarkable assertion is made that not only a geranium, but also *Tradescautia zebrina* has been successfully grafted on the tomato, that is, a monocotyledonous on a dicotyledonous plant. Mr. L. N. Johnson describes the mode of formation and escape of the little-known zoospores of *Draparualdia plumosa*.

THE numbers of the *Journal of Botany* for August and September are chiefly occupied by papers on descriptive botany. Mr. H. T. Soppill gives an account of the life-history of *Æcidium leucospermum*, parasitic on *Anemone nemorosa*.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 25.—M. de Lacaze-Duthiers in the chair.—M. Faye, in presenting the *Connaissance des Temps* for 1896, being volume ccxviii., pointed out some improvements newly introduced. The tables of the fundamental stars contain their magnitudes, their mean coordinates at the commencement of the tropical year, their variation and proper motion, and the dates at which the hour stars pass the meridian at noon and midnight.—The geographical coordinates of Tananarivo and the observatory of Ambohidempona (founded at Madagascar by the Rev. Father Colin), by M. Alfred Grandidier.—On the spectroscopic observations made at the Mount Blanc Observatory on September 14 and 15, 1893, by M. J. Janssen (see p. 549).—Action of the electric arc upon the diamond, amorphous boron, and crystallised silicium, by M. Henri Moissan.—Preparation and properties of crystallised carbon silicide, by M. Henri Moissan.—On the reproduction of oysters in the Roscoff aquarium, by M. de Lacaze-Duthiers. The ostreicultural work at the Roscoff laboratory was undertaken in order to demonstrate the feasibility of the revival of the oyster fisheries on the French coasts on a scientific basis. During the last two years it has been proved that seed oysters could be brought to a high state of development and commercial value in artificial surroundings. It has also been proved that oysters are capable of reproduction in the aquarium. The culture of oysters is at present divided into two main branches, that of producing seed oysters and that of developing the latter into the article of consumption. The Roscoff laboratory is now able to perform both functions. The oysters now completing their fourth year of age and their third of culture in the tank, have produced this year about 5000 young oysters, which will be used as seed oysters for future experiments.—M. Bouquet de la Grye, in connection with a recent work by M. Hatt on the harmonic analysis of tidal observations, announced that the Hydrographic Service of the Marine Department intended to adopt the method expounded, viz. that originated by Lord Kelvin, to the calculation of the *Annuaire des Marées*, and that several maregraphical stations are about to be erected in Indo-China, where the tidal phenomena are very singular.—Circles or spheres derived from any envelope, by M. Paul Serret.—On the glucoside of the Iris, by MM. F. Tiemann and G. De Laire. Iris roots contain a glucoside, iridine, which shows some remarkable properties. Alcoholic extract of iris treated with a mixture of acetone and chloroform of density 0·95, gives *iridine*. It crystallises in small white needles, fusing at 208°, and corresponding to the empirical formula $C_{24}H_{26}O_{13}$. Iridine, heated under pressure with sulphuric acid diluted with weak alcohol, decomposes into glucose and a crystalline body now termed *irigenine*. This forms alcoholic ethers, and also gives rise to two series of acid ethers. Under the action of alkaline hydrates, it absorbs three molecules of water, and then splits into three bodies—viz. formic acid, an acid phenol termed *iridic acid*, $C_{10}H_{12}O_5$, and a phenol termed *iretol*, $C_7H_8O_4$. The latter body is rapidly decomposed by the oxygen of the air when in an alkaline solution. When iridic acid is heated above its point of fusion, it splits into 1 molecule of carbonic acid and a colourless oil distilling at 239° by cooling. It solidifies in large crystals fusing at 57°, constituting a well-defined new phenol now termed *iridol*.—Anatomical researches on the grand sympathetic nervous system of the sturgeon, by M. René Chevrel.—Contribution to the histology of the spongidæ, by M. Émile Topsent.—On two new types of the *choniostomatidæ* of the coasts of France, *sphæronella microcephala* and *salenskia tuberosa*, G. and B., by MM. A. Giard and J. Bonnier.

DIARY OF SOCIETIES.

London.

TUESDAY, October 10.

Photographic Society, at 8 (at the Gallery, 5a, Pall Mall, East.)

WEDNESDAY, October 11.

Photographic Society at 3 and 8 (at the Theatre, Society of Arts, John Street, Adelphi).

THURSDAY, October 12.

Photographic Society, at 3 (at the Theatre, Society of Arts, John Street, Adelphi).——At 8 (at the Gallery, 5a, Pall Mall, East).—Special Lantern Night.

FRIDAY, October 13.

Amateur Scientific Society, at 7.—*Conversazione* and Exhibition.——At 8.—Parasitism, Commensalism, &c.: Mr. Pace.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Inorganic Chemistry for Beginners: Sir H. E. Roscoe and J. Lunt (Macmillan).—Meteorological Observations made at the Adelaide Observatory, &c., during 1884–5 (Adelaide).—Catalogue of the Lepidopterous Super-family Noctuidæ found in Boreal America: Dr. J. B. Smith (Washington).—Method and Results: T. H. Huxley. (Macmillan)—Practical Work in Heat: W. G. Woolcombe (Oxford, Clarendon Press).—The Process of Argument: A. Sidgwick (Black).—A Dictionary of Birds: A. Newton, &c.; Part 2 (Black)—The Discovery of Australia: A. F. Calvert (Philip)—Personal Recollections of Werner von Siemens: translated by W. C. Coupland (Asher).—In Amazon Land: M. F. Sesselberg (Putnam).—Curiosa Mathematica, Part 2. Pillow Problems: C. L. Dodgson, 2nd edition (Macmillan)—Décoration Céramique au feu de Moufle: M. E. Guenez (Paris, Gauthier-Villars).—Les Moteurs à Gaz et à Pétrole: P. Vermand (Paris, Gauthier-Villars).—Biskra and the Oases and Desert of the Zibans: A. E. Pease (Stanford).—An Essay on Newton's "Principia": W. W. R. Ball (Macmillan).—Catalogue of Section one of the Museum of the Geological Survey of Canada: G. C. Hoffmann (Ottawa).—An Introduction to Human Physiology: Dr. A. D. Waller, 2nd edition (Longmans).—Anatomy, Descriptive and Surgical: H. Gray, edited by T. P. Pick, 13th edition (Longmans).—Analysis of Milk and Milk Products: Dr. H. Leffmann and Dr. W. Beam (Philadelphia, Blakiston).—Eleventh Annual Report of the Fishery Board for Scotland. Part 3: Scientific Investigations (Edinburgh, Neill).—On Hail: Hon. Rollo Russell (Stanford).

Pamphlets.—The State of Amazon, Brazil: L. B. Bitancourt.—Fauna and Flora of Norfolk, Part xii. Coleoptera: J. Edwards.—Zur Kenntniss der Postembryonalen Schädelmetamorphosen bei Wiederkauern: H. G. Stehlin (Basel, Schwabe).—Latitudine di Torino determinata coi Metodi di Guglielmo Struve: F. Porro (Torino, Clausen).—Effemeridi del Sole e Della Luna, &c.: A. Manaira (Torino, Clausen).—Osservazioni Meteorologiche fatte nell'anno 1892, All Osservatorio della R. Universita di Torino: Dr. G. B. Rizzo (Torino, Clausen).—Catalogue of Woods Exhibited by the State of Amazon, Brazil, at the World's Columbian Exposition, Chicago (Chicago).—The City of Manáos and the Country of Rubber Tree (Chicago).

Serials.—Zeitschrift für Wissenschaftliche Zoologie, lvi. Band, 3 Heft (Williams and Norgate).—Bulletin de l'Académie des Sciences de Belgique, No. 8, Tome 26 (Bruxelles).—The Free Review, October (Sonnenschein).—Michigan Agricultural Experiment Station Bulletins, 96 to 99 (Michigan).—Zeitschrift für Physikalische Chemie, xii. Band, 3 Heft (Leipzig, Engelmann).—Journal de Physique, September (Paris).—Natural Science, October (Macmillan).—Journal of the Institute of Jamaica, August (Kingston, Jamaica)—Botanical Gazette, September (Bloomington, Ind.).—Medical Magazine, October (Southwood)—Agricultural Gazette of N.S.W., July (Sydney).—Journal of the Royal Agricultural Society of England, third series, vol. 4, Part 3, No. 15 (Murray).—India Weather Review, Annual Summary, 1892: J. Eliot (Calcutta).—Geological Magazine, October (K. Paul)—Geographical Journal, October (Stanford).

CONTENTS.

THURSDAY, OCTOBER 12, 1893.

THE CORRESPONDENCE OF BERZELIUS AND LIEBIG.

Berzelius und Liebig. Ihre Briefe von 1831–1845. Mit erläuternden Einschaltungen aus gleichzeitigen Briefen von Liebig und Wöhler. Herausgegeben mit Unterstützung der kgl. bayer. Akademie der Wissenschaften von Justus Carrière. (München und Leipzig: J. F. Lehmann, 1893.)

THIS most interesting, and, for the historian of chemistry, most valuable little book owes its origin to a sentiment akin to that which prompted the publication of the no less interesting and valuable collection of the letters of Liebig and Wöhler. How important the correspondence of Berzelius and Liebig is to him who essays to write the history of the chemistry of the nineteenth century will be obvious from the fact that this exchange of letters occurred during one of the most eventful decades of the century. It began at the period of the epoch-making work of Liebig and Wöhler on the radicle of benzoic acid, and extended over the time when Liebig was devoting himself, with characteristic ardour and enthusiasm, to the study of animal chemistry and to the applications of chemistry to agriculture. Frequent reference, as might have been expected, is made to these and the many other matters which during that time engaged the energies and occupied the thoughts of Liebig at what was the most active and the most fruitful period of his career. Nor was Berzelius less communicative concerning his own work. Nothing, however, is more characteristic of the difference in temperament of the two men than the manner in which each speaks of what he has done, is doing, or means to do. With Berzelius it is nearly always concerning what he has accomplished, seldom of what he is doing, and still more rarely of what he is going to do. The sanguine, ardent character of Liebig is reflected in almost every letter. He is terribly in earnest on the matters of the moment, and full of enthusiasm and confidence concerning the plans of the future. The philosophic calm which pervades every letter of the great Swedish chemist is a source of wonder and envy to his correspondent.

"I envy you," writes Liebig, "the priceless tranquillity of mind with which you do your work. Pray tell me is it always so with you. Has not the keen desire for discovery not even once made your heart beat quicker? With you there is an ever present intellectual calm."

Liebig wrote as he thought and spoke. "I cannot, like others of cooler blood," he wrote to Wöhler, "keep myself apart from and unidentified with my work: what I do I do with all my faults and shortcomings, but also with all the energy that actuates me."

The letters, therefore, are valuable not only as side-lights on matters which are now regarded as classical in the history of chemistry, but also as evidence of the character and temperament of the two men; and from this point alone they will have a special interest for the historian of science.

The correspondence begins with a new year's letter from Liebig in the January of 1831. The two chemists had made one another's personal acquaintance at Hamburg during the summer of the preceding year, and Berzelius had already expressed to his friend and former pupil Wöhler, the pleasure it had afforded him to meet Liebig. Liebig had perfected his method of organic analysis, and the Giessen laboratory was busily engaged in determining the elementary composition of whole series of organic substances, and he gives in his first letter a brief account of the main results to which he and his pupils had arrived. Berzelius in his acknowledgment congratulates him on his work:—

"It is quite incomprehensible to me how you can have accomplished so much in so short a time."

He tells Liebig of the discovery of a new metal by Sefström, which the discoverer had named Vanadium:

"It is an interesting thing. It will take its place between chromium and molybdenum. Wöhler had well-nigh lighted upon this body. He undertook to analyse lead chromate from Zimapan. He discovered that the substance hitherto regarded as chromic acid was not so in reality, but gave himself no further trouble to determine what it actually was."

Wöhler has himself told us the story, and let the world see the characteristically humorous letter in which Berzelius "chaffed" him for being too lazy to open the door when the goddess knocked.

There is the customary Teutonic contempt for most things Gallic:

"It gives me a real pleasure to read your writings by reason of the love for truth which pervades them—in striking contrast with Dumas, who seems to do everything for show."

In the second letter Berzelius writes:—"Die Unzuverlässigkeit der französischen Analysen. . . . ist eine verdammt curiose Sache," and again Dumas and his pupils are somewhat severely handled. Berzelius is "so satt" with Vanadium that he is constrained to tell Liebig all he knows about this "sehr interessanter Körper." He has just finished his memoir for Poggendorff "in welcher die viele Salzbeschreibungen gewiss manchen Leser einschlafen machen werden." The letter was written with the so-called "vanadium ink," made by adding extract of gall-nuts to a solution of ammonium vanadate. "It flows," says Berzelius, "so extraordinarily well that it is preferable to all iron inks, and fades less easily." Unfortunately Berzelius's expectations respecting the new ink have not been fulfilled: the writing of this particular letter, the editor points out, has become quite yellow, and is difficult to decipher. Liebig does not altogether share Berzelius's opinion respecting Dumas:

"Small as is the confidence I have in Dumas' work, the calculations of this rope-dancer seldom fail in their object: I have assured myself by a direct determination of the vapour density of the non-inflammable gas [phosphuretted hydrogen] that he is right. I am continually annoyed that the fellow, in spite of his wretched and slovenly style of work, should shake masterpieces, so to say, out of his sleeve."

In 1831 Liebig's position at Giessen, in spite of his growing fame, was pecuniarily very poor. He writes to Berzelius:—

"I have latterly taken upon my back a big burden in yoking myself with Geiger as co-editor of his magazine, and all for the sake of filthy lucre. At the small university where I am, where the dullest pedantry sits enthroned, and where natural science is learnt from the Greek authors or from Wilbrand's writings, I should otherwise die of hunger."

However much Liebig may share Berzelius's opinion of French chemical work in general during the thirties, he will hear of no word of disparagement of his old master Gay Lussac, for whom he had the most genuine respect and esteem. A captious remark by Berzelius respecting Gay Lussac at once rouses Liebig, and his impetuous pen dashes off a panegyric which is almost eloquent in the warmth and intensity of its feeling. The only thing to his discredit that Liebig will allow is that, in common with his countrymen, Gay Lussac is not sufficiently attentive to what is done outside France:

"A certain mental indolence prevents the French, to their shame be it said, from making themselves acquainted with foreign work. Gay Lussac shares this failing, and feels that it will gradually effect the ruin and extinction of all scientific growth in France: all his letters to me are filled with complaints on this score, and principally as regards himself. However that is no fault in his character, and can well be forgiven him when one takes his other good qualities into account."

A letter from Liebig, dated December 28, 1831, announces the discovery, and describes the properties of chloral, a "Substanz welche ich, da ich keinen besseren Namen weiss, Chloralkohol nennen will." Berzelius, in his reply, gives an account of his work on tellurium. In May, 1832, Liebig writes that he has begun to work on amygdalin.

"I am on the point of becoming Wöhler's enemy: I see that Fate will not allow either of us to do anything that the other has not already done or is on the point of doing: all originality goes to the devil. He suggests that we should do a joint investigation on bitter almond oil—and just before I got his letter I had written to all the apothecaries I knew of to procure me bitter almond oil, because I too had the matter in view."

What came out of that memorable investigation on oil of bitter almonds no chemist needs to be reminded of. On July 2, Liebig writes that he has been engaged in determining the composition of an "ether-like substance," sent to him by Döbereiner, who had named it "Sauerstoffether."

"Oxygen-ether is no name for this substance. I am, however, very stupid at naming things. What think you of acetal (acetum and alcohol)?"

In more than one of his letters Liebig held out the hope to himself that he might be enabled to visit Berzelius in Stockholm, and do some research in common with him, and he sends to Wöhler for a Swedish grammar. The terrible pressure of his work at Giessen at this time is beginning to tell upon him. He writes to Berzelius:

"I am always ill, and fear my life's thread will not spin out much longer. Each work I undertake makes me worse, and the slightest effort excites me as if I were in a fever. Wöhler and my family tell me daily what a fool I am; however, we shall see. If the journey to Stockholm does not mend me, then I shall never be cured."

Berzelius answers:—

"The pleasure which your news of matters scientific gave me, great though it was, is as nothing compared with that of your promise to spend some months with me and to do a piece of work with me. I have seldom had such a pleasant surprise, but now comes the question: When is this good fortune to befall me? You do not need to speak a word of Swedish to come here. If you wish to learn it, may it be my privilege to be your teacher. Come soon and spend the winter months with me. A Swedish winter is healthier than a German one. Your depressed nervous system will right itself here. We will work, joke, and skate, and not over-fatigue ourselves, and yet labour to good purpose. You will find my laboratory far below your expectation. It is small and badly furnished. But it is just in such a place that one learns to do with little."

The visit, unfortunately, was never made. Wöhler lost his wife in the summer of that year, and in his dejection sought the society of his friend at Giessen. Moreover, the outbreak of cholera at various ports in North Germany made travelling irksome and dangerous. As it was, the two never met again. The correspondence was maintained, with intermissions, down to 1845—that is, until about three years before the death of Berzelius. Little by little misunderstandings arose which eventually ended in coolness, despite the most persistent efforts by Wöhler to preserve friendly relations. The conservatism of Berzelius, who clung, with the obstinacy of age, to views which the rest of the world regarded as obsolete, reacted painfully on the strong-willed, impulsive nature of Liebig, who could as little brook contradiction. There was more than one sharp passage of arms, and at length open rupture. Berzelius made his *Jahresbericht* the vehicle of many bitter attacks on the work of the Giessen school, to which Liebig, restrained by Wöhler, and to some extent swayed by mixed feelings of reverence and pity, seldom replied.

His sentiments towards the great master will be evident from the following excerpt from a letter to Wöhler, with which this most interesting volume closes:

"The opinions and theories of Berzelius were a clear and formal expression of the ideas of his time, and therefore of great value; but they went no further. I will not say that this was a fault, but it would have been a virtue had he possessed a larger measure of that creative thought which I may term the poetry of natural philosophy."

T. E. T.

BACTERIOLOGY FOR THE STUDENT.

Manual of Bacteriology for Practitioners and Students with especial reference to Practical Methods. By Dr. S. L. Schenk, Professor Extraordinary in the University of Vienna; translated from the German, with an Appendix by W. R. Dawson, B.A., M.D. (Univ. Dublin). 8vo. 310 pp. (London: Longmans, Green and Co., 1893.)

THE bacteriological library has recently been enriched by yet another text-book which, although only published in German a few months ago, has already appeared in an English translation. In this work we have the responsibility divided between the author and translator, for the latter has not merely acted as interpreter, but has added numerous foot-notes, besides an appendix intended to bring the book as far as possible up to date, all of which additions are signed by the translator. It does no appear to us that there is much advantage in thus dividing the responsibility in a small text-book which does not contain any original or speculative matter of importance; and in our opinion the reader would have gained had the German original been freely edited by the translator, who should have borne the entire responsibility for the English edition.

The arrangement of the material is much the same as in most previous works on this subject, but the description of a larger number of micro-organisms, considering the size of the book, is attempted. In this matter the time has now come for a new departure, for with the continual additions to the number of known bacterial forms, it is both impossible and undesirable that the descriptions of all of them should find place in the body of a text-book. For the purpose of illustrating the principles of bacteriology, comparatively few forms need be described in detail, whilst for an account of those forms which are of secondary importance, special works should be consulted. A work of this kind, which endeavours to describe in the tabular form, every micro-organism hitherto discovered, fortunately already exists in the shape of Eisenberg's "Bakteriologische Diagnostik" (Hamburg and Leipzig, 1891), so that the necessarily brief and imperfect descriptions of bacteria which are to be found in small text-books, like the one under review, become worse than valueless, inasmuch as they take up space which should be devoted to the discussion of general principles. Now, in this latter particular the work before us is specially weak; not only is the preliminary chapter on the "general morphology and biology of micro-organisms" very scanty, but the introductory matter at the commencement of the several chapters is generally also quite inadequate. Thus, for instance, in the chapter on the micro-organisms of soil we find no less than two pages devoted to the description of such obscure and unimportant forms as *bacterium mycoides roseum*, *b. radiatus*, *spinosus*, *liquefaciens magnus*, *scissus*, and *clostridium fœtidum*, whilst there is absolutely no mention of the bacteria producing nitrification, nor of the organisms occasioning the tubercles in leguminous plants, which are of such enormous importance, both from a practical and theoretical point of view.

In that portion of the book devoted to the practical methods, we find very ample descriptions of the mechanical details for staining bacteria, but the account given of the principles upon which these methods rest is very meagre, and often betrays much ignorance of chemical principles in general. Thus, what are we to think of the statement that "*aniline oil* and *phenol* are the mordants (*sic*) most used in bacteriological research"? Surely a few words from a competent chemist would be calculated to put some order and arrangement into the wilderness of empirical staining recipes with which the student is confronted, and would prevent such inaccuracy in the use of old-established technical terms. A mistake of more practical importance, which a little chemical knowledge again would have rendered impossible, is the statement on page 20, that plates intended for culture may be sterilised "after being cleansed with alcohol and corrosive sublimate"; in this case, however, we are inclined to believe that the "alcohol" being placed *before* instead of *after* the "corrosive" sublimate must be a *lapsus plumæ* which has failed to receive correction in the proof.

Of the same order, again, is the statement that some bacteria "cause a splitting-up of urea into ammonium carbonate"; surely if the reaction in question, and which consists in the adding on of two molecules of water,

$$\underset{\text{Urea}}{CN_2H_4O} + \underset{\text{Water}}{2H_2O} = \underset{\text{Ammonium Carbonate,}}{CN_2H_8O_3}$$

can be described as "a splitting up," the addition of two chimneys to a house might as logically be called a disruption of the building!

The author in his preface states that "conformably to the scope of a hand-book like the present, all references to the literature have been omitted," but the names of investigators have been freely introduced in the text, and in some cases they have been selected apparently without a due knowledge of the literature. Thus, from the text (p. 124 and p. 156) it would appear that it is to Rubner and Kirchner that we are indebted for the discovery of the great bacteriological efficiency of the soil as a natural filtering medium, whilst we were certainly under the impression that Pasteur, not to mention others, showed the bacteriological purity of spring and deep well waters before the names of the above gentlemen were known to the scientific world. In the same way the discovery of the increase in the efficacy of chemical disinfectants by moderately raising the temperature is ascribed to Heider, whilst it was really first made by Dr. Wynter Blyth, some eight years ago, but his paper, which was published in the Proceedings of the Royal Society, was doubtless unknown to both Heider and the author of this book; but the translator might, in the interests of British science, have seen that the papers in that and other English media of publication had received their due. In the chapter on Morphology we find no mention of the researches of Ray Lankester and others on the polymorphism of beggiatoa, which are of such interest in connection with those phenomena of variation in both the form and function of bacteria which are now beginning to receive the serious attention of investigators; nor is there, indeed, any special reference to this subject of variation, which at the present time is certainly one of the most important in the whole domain of bacteriology.

A considerable part of the translator's appendix is devoted to the bactericidal action of light; here again we think that the work of the original discoverers, Downes and Blunt, has been inadequately appreciated, for these investigators practically explored the whole subject in outline, and the more recent researches have principally consisted in a confirmation of their results, and in filling in details; thus they showed that the bactericidal action of sunlight is independent of rise in temperature, that the most refrangible rays of the spectrum are the most active, that their effect, moreover, is highly favoured if not entirely dependent on the simultaneous presence of oxygen, and, further, that the bacteria may be destroyed by light in the absence of any culture-medium, but that they are more resistant to light when immersed in water or very dilute culture material. Again, we find no reference to one of the most interesting recent additions to our knowledge of this subject, viz. the discovery by Laurent that exposure to sunlight causes some chromogenic bacteria to lose their power of producing pigment, either temporarily, as in the case of the *bacillus prodigiosus*, or even permanently, in the case of the *bacillus ruber* of Kiel. We are, therefore, surprised at being categorically informed, both in the introduction and in the appendix of this work, that pigment is formed especially under the influence of light, a statement which is entirely out of harmony with the observations of Laurent, and for which the experimental foundation should have been carefully set forth.

These and other points of a similar character will doubtless be rectified by the translator in preparing a second edition, which it would be well to amplify with references to literature, with which even an elementary student in a new science must at once be made familiar. The illustrations are in the majority of cases very good, and contrast most favourably with those we have seen in some recent works of the kind in which photographic representations have been attempted. The coloured prints of cholera and typhoid bacilli are especially excellent.

OUR BOOK SHELF.

Exploration of Mount Kina Balu, North Borneo. By John Whitehead. (London: Gurney and Jackson, 1893.)

MR. JOHN WHITEHEAD belongs to the much-maligned class of field-naturalists. For the purpose of obtaining a knowledge of the ornithology of Mount Kina Balu, he spent nearly four years collecting in the region, and accumulated a large number of new species. In addition to visiting North Borneo, he stayed some time at Java and Palawan, and made an expedition into the State of Malacca. The rather cumbersome volume before us recounts the story of these explorations. It consists of 192 pages of general description and 115 pages of matter reprinted from the proceedings of various Societies. Thirty-two excellent plates illustrate specimens from the extensive zoological collections made by Mr. Whitehead, and the places and peoples seen by him. It need hardly be said that these add considerably to the value of the book. Several woodcuts are also included. It would be ungracious to find fault with Mr. Whitehead for looseness of expression, since he craves indulgence for his "literary shortcomings." He found it far easier to explore an unknown tract of country than to write an account of his travels. Like some other travellers who have given to the world accounts of their wanderings, Mr. Whitehead dwells too much on trivialities. But for all that, there is much that is new and interesting in the book, and one cannot but admire the indomitable spirit which carried the author through numerous difficulties, and enabled him at last to reach an altitude of 13,525 feet on the mountain of Kina Balu.

Pillow Problems. Curiosa Mathematica, Part II. By Charles L. Dodgson, M.A. (London: Macmillan and Co., 1893.)

IN these pages we have a series of problems worked out, or, as the author says, "nearly all thought out during sleepless nights." In the preface he informs us the exact method of procedure, and the way in which he obtained his results. The problems are about seventy in number, and deal with many branches of mathematics, but chiefly with algebra, plane geometry, and trigonometry. The order of the three and only chapters is as follows: questions, answers, and solutions; and he explains the reason for this peculiarity in the preface. Considering the problems themselves, one is apt to think that some of them at least are not so very hard, but the publication of them will be found very interesting and perhaps useful to those of ordinary mathematical powers, who may like to follow the same routine way of thinking as that adopted by the author.

The A B C Five-Figure Logarithms. By C. J. Woodward, B.Sc. (London: E. and F. N. Spon, 1893.)

THIS small book of logarithms may be said to be a second edition of the tables previously published by the author. In addition to the tables of mantissæ of numbers, the same A B C system has been applied to logarithms of arc functions, with only a slight difference in the method. Besides these the square roots of numbers (from 1 to 100) to three places of decimals are given, and a table of "numbers often wanted," and of the densities of gases, weights and measures, &c. To facilitate the finding of the logarithms, &c., a lateral index is adopted. Besides being a compact and convenient set of tables, the worker will find them easy to use, and accurate enough for such calculations as are generally met with in the physical laboratory, the class-room, &c.

Enunciations in Arithmetic, Algebra, Euclid and Trigonometry. By P. A. Thomas, B.A. (London: Macmillan and Co., 1893.)

IN these pages one is treated to a selection of some of the chief questions that relate to Arithmetic, Algebra, Euclid, and Trigonometry. Stress is laid on the more elementary parts of each subject, and several typical problems are inserted. The latter relate chiefly to the arithmetical and algebraical sections, while the Euclid section is accompanied by important riders. The book should prove acceptable to those revising these subjects, whether for examination or not, and will be, both for teachers and taught, a useful companion to the text-books in use.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Thoughts on the Bifurcation of the Sciences suggested by the Nottingham Meeting of the British Association.

THE opening paragraph of the President's address contains this sentence: "We have come to learn what progress has been made in departments of knowledge which lie outside of our own special scientific interests and occupations, to widen our views, and to correct whatever misconceptions may have arisen from the necessity which limits each of us to his own field of study."

A most worthy and attractive ideal. Something of this kind of intersectional information does go on at these meetings; but to how small an extent! It may be said, indeed, that except for the presidential address and the two evening lectures, everyone sticks to his own section, and discusses matters lying in his own groove.

This state of things is perhaps inevitable, but it is none the less to be regretted. It is extremely difficult for anyone actively engaged in the work of any one section to attempt to attend any other. I myself used to make the attempt, but concluded that the results were too precarious and uncertain to be worth the dissipation of energy involved, and have now abandoned it. Yet there can be little doubt that if the state of things postulated by the President were feasible in practice it would be a distinct gain.

But it would seem as if the modern tendency were all in the other direction. Papers in the two great scientific departments are read as far as possible on different days at the Royal Society, and are published in separate volumes. Such an arrangement is decidedly convenient: I am not repining at it. The

Royal Society type of paper is almost necessarily unintelligible to any but specialists, perhaps sometimes even to them.

But the arrangement should not be regarded as anything but a lamentable necessity. If a more conjoint character could by any device be given to the meetings of the B.A. it would be an excellent thing: so it seems to me.

Whether the British Association can or cannot act as a connecting link between the sciences, there is no doubt but that the pages of NATURE do so act; and long may it be before NATURE (I mean the publication) finds herself also bifurcated or otherwise subdivided, and we on either side cease to hear even an echo of what the other side is talking about.

Perhaps few are able to say that they read NATURE all through as Mr. Darwin did, but we all have the chance of doing so; and I hope it is the practice of the biological side to communicate to its pages at least an epitome or a popular account of all the researches which have a wide embracing interest.

Much that the chemist does—still more that the biologist does—we of the physical camp do not care to hear; partly because we might not understand it, chiefly because the research lies so far from the field we are at present occupied in cultivating, that we can perceive none of the connecting links.

But some of the problems on which the biologist—especially perhaps the physiologist—is engaged are, or might easily become, of supreme interest to physicists; notably everything connected with sense organs and the "mechanism" of sensation.

The fear is lest we drift apart so far that we cease to understand each other's language.

The current language of physics consists mainly of adaptations of simple English phrases. It is full of common words, redefined and made definite in connotation. We do indeed use the word "coefficient" occasionally, but we are getting ashamed of its length and high-falutin' character. We got it from the Mathematicians. We have also a few other long words, as Electricity and its derivatives, which we sometimes try to abbreviate without much success. We got them in the Middle Ages. But the words we coin now are as nearly monosyllabic as possible, and as near akin to the ordinary usage of language as may be.

The current language of biology is quite different. Its sentences, as exemplified in parts of the presidential address, are highly dignified and elaborate structures, not wholly different from a once more prevalent German model. Its words, especially its new words, are hendecasyllabic or, at any rate, polysyllabic. They are extremely classical, and as unlike the language of daily life as can be contrived. This is done of good set purpose, viz. to keep free from the misunderstandings arising out of the attempt to give to popular words a scientific, *i.e.* an accurate, meaning.

I suppose it is inevitable, and no doubt biologists know what is best for their own science; I only lament it because it seems likely to retard that free intercommunication between the sciences which many of us would like to see made more possible than at present it is. I shall have the President with me here; but may I put a question to him without profanity? May I ask him if he can imagine a biologist asking about a process, "What is the go of it?" I conjecture, but perhaps I am wrong, that if a young biologist wanted to know more about a most important and interesting process occurring in the blood, he would ask, "What mechanism do you consider it was which supplied the chemiotactic stimulus impelling these leucocytes towards the morbific microbes which they are devitalising?"

I do not complain of this language—very likely it is well suited for home consumption—but it does seem to render intercommunion difficult.

Now, for instance, I am anxious to learn the most recent view of biologists on the subject of life, or vitality, or vitalism, or whatever word conveys the hypothesis that the life of an organism is something different from the chemical and mechanical activities of its tissues. I see that the President touches on this very subject, but somehow I cannot seize concerning it any distinct idea, though I rejoice to see his warning against the misuse of the terms "mechanism" and "mechanical." The term "mechanical" is regarded by physicists as the *ne plus ultra* of explanation, and it is unlikely that any explanation of physiological processes will skip the intervening chemical and physical stages, and land itself straight in simple mechanics.

But I wonder if I am right in supposing that the definition of life, given apparently by Treviranus, satisfies the modern biologist, viz. (I put it only in paraphrase, for more exact wording see NATURE, September 14, p. 464), "that property of an organism which enables it to respond similarly to a variety of different stimuli"; because a steam engine or any other prime mover can do as much as that. It matters nothing by what means the throttle valve is opened, whether by the proper driver, or by a larky boy, or by a piece of string, or a falling weight, or an electric current; the result is the same—wheels go round.

This property of responding to stimuli, and responding always in the same way if at all, may be characteristic of a clock-work mouse, but surely it is not a special peculiarity of *life*. If a muscle can only twitch, then, however you tickle it, it must either twitch or do nothing.

But life surely is something other than a power of response to a stimulus; it is more like a something which directs the stimulus, more like the driver who decides whether the throttle valve shall be opened or not. But it is absurd for me to attempt to answer such questions. I only want to ask them: all I clearly perceive from the physical standpoint is that live creatures have the power of directing energy into otherwise unoccupied channels, and that life in itself, whatever it is, is *not* a form of energy.

But this leads me to a subject which though apparently trivial may, if not attended to, have serious or at any rate inconvenient consequences, I mean the occasional misuse by one science of the language of another science.

The term "energy" is a physical one given us by Thos. Young, and it has been fought for by us through a great part of this century. It will be wanted seriously by Physiologists before long, in its proper sense, and it will be a thousand pities if they misuse it.

If it be urged, "but Helmholtz used the term *specific energies*," I reply yes, a long time ago, and so also he used the phrase, *Erhaltung der Kraft*. But precision in the use of the term energy is of comparatively modern growth, and every one now translates *Erhaltung der Kraft* as "conservation of energy." So, also, I venture to think, they should usually translate the phrase "specific energy" by the words *normal activity* or *normal reaction*. Of course if normal activity of an organ or tissue does not represent the thing meant, that is another matter—so far as I can judge, it usually does; but whether it does or not, I am clear that specific energy is usually wrong. There is one definite theory or hypothesis, to express which the words energy in some form would be correct—viz. when it is meant to assert that, for instance when light falls upon the retina, all it does is to pull a trigger, and the explosion or nerve stimulus which results is due to energy in or near the nerve ending itself. If that is a true statement of the case, and there must be a great deal to be said for such a view, the latent energy of the organ can no doubt be measured. But inasmuch as energy is all one thing in many forms, the adjective *specific* is better omitted; moreover the phrase is not usually limited to this particular hypothesis; and by "the specific energy of an organ," is usually meant, not anything quantitative, but simply the mode in which it normally reacts.

Another case of terminology occurs to me. For specification of small lengths microscopists have introduced the term *micron* for a thousandth of a millimetre, or a millionth of a metre; and very handy is both the magnitude and the name, and I hope physicists will adopt it. But everyone should consent to use it in the same sense. There was a discussion about it in the pages of NATURE a few years ago, but I am not sure that the usage even now is quite distinct. Many biologists call it a micro-millimetre, which it is not; and though they may mean the same thing, it can only be by an erroneous, because unconventional, use of the prefix micro. All these things are conventions, and once made the convention should be rigorously adhered to. Sometimes the word is written *micro* instead of micron; a very small divergence, but better avoided. Either term will do perfectly well, but not both.

May we understand then that a micron is a micro-metre, or a milli-milli-metre, or 10^{-4} centimetre; and that a millimicron is a micro-millimetre, or 10^{-7} centim.?

And may I incidentally protest against too much public use of the meaningless and wasteful symbols μ and $\mu\mu$ for these two lengths. If these symbols are found too handy in technical microscopy to be abandoned, they must be used there; but they should never be allowed to obtrude into anything intended for the general reader, nor for workers in other departments of science.

I trust that physicists will agree with me in this. I know that some Electricians try to sin in a similar way, by writing 6ω when they mean 6 ohms. But with all deference to any individuals who may have allowed themselves carelessly to drift into this practice, it is a thoroughly bad precedent. We shall soon be having 12*a* and 5*v* and ·3*h* for current and voltage and inductance respectively; a simple specification will look like algebra, and algebra will look like gibberish.

Similarly the custom of writing M for a millionth of an atmosphere, or 1 barad, is a worrying custom. Let us always have names for units with which we have much to do, but never single letters. Single letters have to serve a far more important purpose, that of denoting the quantities themselves—the whole of a quantity, numerical part, unit, and all.

This last is an old hobby of mine. Ever since my brother showed me the advantage of consciously interpreting algebraical symbols as standing for concrete quantities, and not merely for abstract numbers, the advantage of doing so has presented itself to me with cumulative force. Most physicists are, I think, now of a similar opinion, if they have thought at all about the matter, and Prof. Greenhill is being left almost alone in his state of grievous error; I would say heresy, but that I fear he has some of the pure mathematicians with him for company.

I have dragged Prof. Greenhill in because I want to deny the extraordinary assertion which he makes in an article on page 457 of your issue for September 14, viz. that I would like to "banish the word *hundredweight* from our language." On the contrary, for the specification of loads I have always found it a very convenient word; and if architects use it thus, for pressure on foundations, so much the better. I know what he is referring to—a part of my book on mechanics where I am instructing youth in the meaning of the term *mass*, and the difference between mass and weight. Till they are clear on this point I say that "hundredweight" is a term better avoided for the present. I should, for instance, recommend its avoidance for the present by Prof. Greenhill.

But to return to Dr. Burdon Sanderson's address, which it is perhaps evident from a former part of this article that I have been trying to read, there are two small points on which I would ask a question. First, with regard to totally colour-blind vision. If a person sees all the world in shades of gray he may properly be called colour-blind, in one, and that the most important, sense; but it does not seem to me to follow that he necessarily appreciates white, still less that he proves a specific white sense in normal eyes. On the orthodox theory, as held by physicists, such an eye would strictly be called monochromatic; one only of the three colours would be seen, and which it was would matter nothing to the seer, though it might be ascertained by studying his spectrum vision which the one colour was in any given case. I believe that Abney and Festing found it usually blue. But as regards the psychological impression produced by mono-chromatic vision on the seer, its indiscriminating monotony would obviously result in total absence of colour perception. One colour sensation is psychologically the same as none.

The other question is whether it is useful to distinguish between "physical light" and "physiological or subjective light." The term *light* applies to the stimulus as far as the retina, but after that is it not better called either *sight* or some other and more impressive-looking word, beginning with *photo* or *neuro* and perhaps ending with *taxis*, signifying the specific disturbance of the optic nerve and brain centres. These terms light, heat, sound, &c., have always been ambiguous; but, if needful to discriminate, they had better perhaps now be handed over entirely to physics, to signify monosyllabically the external physical stimulus; while fresh words are coined for the physiological, and again, where not already existing, for the psychological, result.

I trust that this letter has not the appearance of undue presumption; the whole of it is written in the key of interrogation.

OLIVER J. LODGE.

British Association: Sectional Procedure.

MEMBERS of the British Association often entertain schemes for the improvement of sectional procedure, which rarely, so far as I have seen, commend themselves to the good opinion of the organising committees. I beg leave to produce one scheme more. Whether the remedy is practicable or not, I am quite sure that the grievance I have to point out is a real one.

Every member of the Association has suffered from the great uncertainty as to the hour at which a particular paper will come on. At the recent Nottingham meeting I was unlucky enough to spend one morning to no purpose. I had a direct interest in two communications; one was not reached that day, the other was taken as read. There is no care taken to prevent such accidents, and yet it would have been easy to provide against the second one at least by marking the communication as "Title only." The other case is of greater, but not, I think, of insuperable difficulty. The remedy which occurs to me is this: a fixed time should be assigned to communications which in the opinion of the Sectional Committee are of special interest and importance. There might be at least two absolute fixtures in each day's proceedings, when members would know that nothing would be allowed to interfere with the punctual production of certain papers or addresses. I should be inclined to mark these by some distinctive title, such as "Address by request of the Section." It seems to me very desirable to send out special invitations before the meeting to persons who could communicate interesting results; and I have little doubt that a fixed time would often lead to acceptance by persons whom the Sections would be glad to hear, but who rarely or never appear in the programme under the existing system. What is bad for the audience is bad for authors too, and after an author finds that his communication is addressed only to people who come to hear something else, and to people who in their despair are working through the entire list, he ceases to offer himself.

If the facilities granted to pre-arranged addresses should lead to a stricter treatment of trivial papers and business matter of no direct scientific interest, the Sections would not suffer.

L. C. M.

Orientation of Temples by the Pleiades.

EIGHTEEN months ago, while at the Mena House, Cairo, I came across a back number of NATURE, which contained an article on "The Origin of the Year," in which reference is made to the orientation of some Egyptian temples, and I suggested that inquiries should be made as to whether they were not in some cases oriented by the Pleiades. I had not then seen the numbers that referred to stellar orientation.

A pamphlet of 105 pp. was privately printed by myself *thirty years ago* (!) for my own use in the prosecution of "A Comparison of the Calendars and Festivals of Nations," with special reference to the Pleiades.

Since that pamphlet, and a second, of about 20 pp. on cycles regulated by the Pleiades, were printed, I have collected a great deal of further data confirming the conclusions arrived at in 1863. Müller says, in his Religion, &c., of the Dorians, I. 337, that the famous eighth-year cycle, which was in general use in Greece, was luni-sidereal, and regulated by the Pleiades, and that the great feasts of Apollo at Delphi, Crete, and Thebes, were arranged by it. He also states (p. 338) that there are vestiges of a sacred calendar in general use in Greece in early ages based on this cycle, but that it fell into disuse, and, in consequence, the Attic festivals and months were thrown into confusion. He had previously stated that the Olympiads were based on the eight-year cycle. Apollo, generally assumed to have been essentially a solar deity, though he evidently was originally a type of Karlikeya, was a god of the Pleiades, and hence the seventh day was sacred to him at Athens. As those stars were the daughters of Atlas, the forty days during which they deserted the nightly sky were spent by Apollo in dancing and singing among the Hyperboreans of Marlas. When the rising of the Pleiades at early morning took place, he returned. In 1882, at the American Association, I showed that he is still remembered south of the Atlas as "Apōlo, a good god, who comes and plays upon the harp." But in the lapse of centuries the Pleiades seemed to go astray, and were forgotten, and, strange to say, Athenæus was forced to treat the history of the Pleiades as a bit of obsolete folk-lore. In discussing the subject of the two groups of *Peleiades* on the handles of the divining cup of Nestor, he says that it is a mistake to suppose that Homer by *Peleiades* meant "doves" (a mistake which Mr. Gladstone has also made in his Homeric Studies), and he explains that the cup had two clusters of seven stars represented on it. Many persons, he says, are puzzled at the prominence thus given to those stars, but in early times they were regarded as very important, and left their impress on early mythology, and he also shows that they once regulated the time of sowing, and the season for navigation. He goes at great length into the question in his *Deipnosophists;* and I invite the attention of those who wish to know something as to the early history and influence of the Pleiades to the work in question.

As Plutarch says that the great feast of Isis was always held at the time "when the Pleiades are most conspicuous," and I found that the month of Athyr, in which it was held, was described as "the shining season of the Pleiades," I sent, in 1865, a copy of my pamphlet to Prof. C. P. Smyth, before he went to Egypt, and invited his attention to the probability that those stars were in some way indicated by the Great Pyramid.

The recent discovery by Mr. Penrose that the Hecatompedon site of the Parthenon, and other archaic Greek temples were oriented by the Pleiades, lends a new interest to this subject.

This diversity of orientation has had a far wider range than has been supposed, for nearly forty years ago it was noticed in the Mississippi mounds by Squier and Davis; and was long ago detected in several early churches of the south of England, a very remarkable fact, which I think was referred to at the Anthropological Institute. As it greatly surprised and interested me, I made a careful note of it when it was published, which I regret that I cannot now hunt up, as I am preparing to leave England for the winter; but as the point cannot have escaped the attention of others, some one among your readers will perhaps be able to give you further information as to it.

NATURE of August 31 contains an interesting letter on the importance of the study of the date of the birth of Rama by competent astronomers. For several years I have been trying to find out what was the precise time of the year when Kartikeya was born—"*The Birth of the War God*" does not refer to it. There is a most interesting subject which is new to science, the connection of the Pleiades with the nativity of divine heroes. I think I can at last supply a clue to the *Star of Bethlehem* (which Kepler imagined to have been a conjunction of planets!) in "*the Christmas Stars*," of the negroes, and other African races.

September 7. R. G. HALIBURTON.

Early Chinese Observations on Colour Adaptations.

IT seems of interest to record that the Chinese, neglectful of the sciences as they are nowadays, nevertheless suggested the Darwinian interpretation of animal colours as early as the ninth century A.D.

Twang Ching-Shih, in his Yú-yáng-tsáh-tsú (Maútsin's edition, book xvii. p. 7 Kyōto, 1697), describes a trap-door spider as follows:—"Whenever rain has fallen, the ground facing my book-room has plenty of the 'tien-táng' (that is, the 'tumbling-defender'). Its nest, commonly so-called, is as deep as an earthworm's hole, and the network is finished in it. The earthy lid of the nest is quite even with the ground, and of the size of elm-samara. The animal turning upside down, guards the lid, and thus watching for the appearance of flies and caterpillars, it readily turns up the lid and catches them. As soon as it retreats the lid is closed again. The lid is coloured like the ground."

Apparently from this and other facts the observer has attained a revelation of the truth, which he expresses thus:—"In general, birds and mammals necessarily conceal forms and shadows by their assimilation with various objects. Consequently, a snake's colour is similar to that of the ground; the hare in the Imperata-grass is unavoidably overlooked, and the hawk's hue agrees with that of the trees."

Twang Ching-Shih was a man of great erudition, and versed in poetry; he died in the period of Hwi-Cháng (841–846 A.D.), leaving us the work cited above, consisting of thirty books. It is highly commended by Sie Tsái-Kang, a distinguished encyclopædist of the seventeenth century A.D., as one of the two "Crowns of all Miscellanies."

KUMAGUSU MINAKATA.

15, Blithfield-street, Kensington, September 26.

A Remarkable Meteor.

A METEOR of surpassing brilliancy and great size was seen here on the 1st inst., just before 10 p.m. The course seemed to be from westwards towards the north-east. The meteor was of a vivid blue colour, and it lighted with its splendour the whole visible horizon. In a clear blue sky the harvest moon, on the wane, was at the time shining brightly.

On disappearance the blue fiery ball left behind it for some seconds a long luminous trail, like that which follows the flight of a rocket. Travelling apparently at a considerable height, the ball was observed at much about the same time at Llanefydd, amongst the hills in North Wales. A correspondent writes thence: "Last night (the 1st inst.) I witnessed a remarkable meteor. I always, these moonlight nights, go up the Freith just before 10 p.m. I went up last night; it was just like day (the effect of the moon shining in the clear air of the hills). Just when I was on the top, turning to come down, and looking up the valley, the place suddenly became lit up with a blaze of intense blue light. I thought it was a tremendous lightning flash; but as it lasted too long for that, I looked, and then saw what it was. There was a meteor falling just behind Tan-y-Gurt Mountain, as bright apparently as the sun. It was a globe of flame as large as an ordinary football, and of a light blue colour. I saw the ball for about as long as a rocket takes when falling. The ball was very much like an enormous rocket, and afterwards there was an appearance just like a stick falling from the flame. The meteor came from the west, travelled towards the north-east, and fell perpendicularly." My correspondent adds: "The meteor did not shoot from any radiant known to me."

Worcester, October 4. J. LLOYD BOZWARD.

THIS meteor was distinctly seen at Driffield, East Yorkshire. It proceeded from a point about 45° altitude in the west, and passed towards south-south-west at an angle of about 40°, disappearing at an altitude of about 20° in the south-west. Duration two seconds; slow motion. A trail of yellowish-red sparks appeared on both sides (top and bottom) as it travelled forward. Several letters appear in the *Yorkshire Post* of the 5th inst. from persons who saw it in Yorkshire.

J. LOVEL.

TERTIARY AND TRIASSIC GASTROPODA OF THE TYROL.[1]

THOUGH much has already been done for continental palæontology, a great deal still remains to be accomplished. The earlier workers in the field laboured under the disadvantage of having to deal with comparatively scanty material, mostly scattered in private collections over large areas at a time when intercommunication was far from easy. Nowadays these old collections with their type-specimens have for the most part found their way into the museums of the principal cities. Moreover, not only may they freely be examined on the spot, but sometimes, we are glad to know, are allowed, under proper precautions, to be removed for the purpose of comparison with types preserved elsewhere. These altered circumstances and the acquisition of new specimens have not merely aided, but even provoked the revision, rectification, and completion of the labours of bygone times.

The two articles before us are examples—the one of supplementary, the other of both supplementary and revisionary work.

To take them in their order:—

Dr. Dreger's paper is the first of a projected series in which it is intended to treat of the fauna of the tertiary beds at Häring in so far only as it has not already been dealt with. Any conclusions Dr. Dreger may have come to concerning the exact age of these deposits, which Gümbel considered to be the equivalents of our Bembridge and Headon beds, are reserved till the whole of the material has been disposed of.

The fossils are in a very bad state of preservation, being much crushed, distorted, and broken: the more

[1] "Die Gastropoden von Häring bei Kirchbichl in Tirol." Von Dr. Julius Dreger. (*Annalen des K.K. Naturhistorischen Hofmuseums*, Bd. vii. 1892, pp. 11–34; Pls. i.–iv.). "Die Gastropoden der Schichten von St. Cassian der südalpinen Trias." Von E. Kittl. II. Theil. (*Ibid.* pp. 35–97. Pls. 5. (Wien: A. Hölder.)

delicate parts, such as the outer lips, long anterior canals, where such existed, and any spiny projections, are usually missing. With such unsatisfactory material to work upon it is little wonder the author has in many cases been unable to come to any definite determination as to the species; indeed in several instances, most wisely, no specific identification is attempted.

The list given at the end shows 114 forms, including 15 which are described as new; but of these some had better have been left unnamed till more perfect examples were forthcoming, whilst in certain instances, such as *Voluta stromboides*, one feels sceptical, if any reliance may be placed on the figure, as to the very determination of the genus. Nor is the description of these new species always adequate: that of *Trochus demersus* being especially insufficient. One of the figures is that of an interesting example of *Xenophora*, considered by Dr. Dreger to be very near to, if not identical with, *X. subextensa*, d'Orb. This individual must have possessed a somewhat fastidious taste, for in lieu of the ordinary fragments of shell and other oddments that its kindred usually love to attach to their tenements, it selected for the decoration of its house the fusiform shells of *Cerithium* and *Pleurotoma*, which it disposed radially, attaching them by their apices. This unwonted arrangement is paralleled in a recent example of *X. pallidula*, Reeve, dredged off the Philippines during the *Challenger* expedition, the decorative shells being those of *Terebra* and *Pleurotoma*.

The nomenclature employed by Dr. Dreger is not in all instances up to that standard of exactitude which the present-day devotees of the law of priority demand, and undoubtedly will bear revision, and so, too, we regret to see will his synonymy. Dr. Dreger's principle of giving in synonymic references the name of the authority cited for the species by the author who is quoted is decidedly the fairest and best system and one which for our part we would gladly see universally adopted. By way of instance a portion of the synonymy of *Cassidaria ambigua*, Brander is here given, omitting however for sake of brevity the references to the several papers:—.

1776. *Buccinum ambiguum*, Brander, &c.
1812. *Cassis striata*, Sow., &c.
1843. *Cassidaria ambigua*, Brander, Nyst, &c.
1851. *Cassis affinis*, Philippi, &c.
1854. ,, ,, ,, E. Beyrich, &c.
1861. ,, ,, Beyr., Gümbel, &c.
1864. ,, ,, Phil., Giebel, &c.
1865. ,, *ambigua*, Sol., v. Koenen, &c.

Unfortunately our author has not been as careful in following out his own system as he should. Moreover the reference to the first description of a species is frequently omitted altogether; the descriptions from Brander's "Fossilia Hantoniensia" are sometimes attributed, and correctly, to Solander, and sometimes, as in the example quoted, to Brander: the synonymy is frequently unduly swollen by references to mere lists such as that in Gümbel's "Geognostische Beschreibung."

The paper concludes with a table showing the distribution of the 19 species which are also known to occur in other localities. This is supplementary to the similar table given by Gümbel (*op. cit.* Abth. i. pp. 608–9).

Turning to the second article, it is needless to remark that the St. Cassian beds must ever remain a source of interest to the geologist, not only on account of the remarkable mixture they offer of palæozoic with mesozoic forms of life, as evinced by the occurrence of *Orthoceras* on the one hand and *Ammonites* on the other, but also from the fact that so large a number of fossil species are peculiar to them.

The St. Cassian fauna has been treated monographically by Münster in his "Beiträge zur Petrefacten-Kunde" (Hft. iv., 1841), by Klipstein in his "Beiträge zur Geologischen Kenntniss der östlichen Alpen" (1843), and by Laube in a series of papers published in the "Denkschriften der k. k. Akademie der Wissenschaften, Wien," between 1865 and 1870. Although the last-named palæontologist added very largely to the number of species known, the subject was far from being exhausted, and the accumulation of fresh material has enabled Dr. E. Kittl to still further augment the list of Gastropoda by the addition of many new forms, mostly of small size and many of very great beauty.

The first part of this paper, published last year in the preceding volume of the same serial, contained descriptions of all the species of Scaphopoda and of Gastropoda Prosobranchiata from *Patella* to *Clanculus*; the second portion now before us embraces the families represented in these beds between and including the Neritidæ and the Littorinidæ, and introduces two new genera—*Palæonarica*, in Neritidæ, and *Pseudoscalites* in Trichotropidæ.

The classification and nomenclature followed, it should be stated, is that adopted by Zittel in his well-known "Handbuch der Palæontologie," and of course shares the merits and demerits of that system. Only in two instances does our author depart from his model. The genus *Chilocyclus*, Bronn, is restored on the ground that it is distinct from the *Cochlearia*, Braun, to which Münster had referred the St. Cassian species. In the same way *Delphinulopsis*, Laube, which has been set aside as embracing forms referable to two genera—*Neritopsis* and *Fossariopsis*—is re-established by Kittl for reasons which are too technical to be dwelt on here, but which we confess do not seem entirely satisfactory.

To criticise so elaborate and careful a work as this in detail is, indeed, not possible without seeing the actual specimens, however good the figures and lucid the descriptions may be, and we fear it would sound ungracious when so much is vouchsafed us to wish that some of the new types had been less fragmentary, or to express an opinion, however guardedly, that some of the specimens figured, besides that so acknowledged, convey the impression of being immature and possibly the fry of other species.

The difficulties that have to be contended with in the production of a work of this sort are far from small, and the conscientious palæontologist must frequently be at his wits' ends to decide whether he shall refer a given example, especially if imperfectly preserved, to a known genus from the typical forms of which it differs considerably, or shall incur the odium of adding another name to an already overburdened nomenclature.

Take such an instance as that here afforded by the genus *Scalaria* (or should we write *Scala?*). Amongst the species are forms which the synonymy shows were referred by so able a palæontologist as Laube to the very distinct genera *Turbo*, *Trochus*, and *Turritella*. A glance at the figures shows how far these forms depart from those we have been accustomed to associate with the old familiar Wentle-traps, and it is little wonder that Dr. Kittl suggests the desirability of establishing a new subgeneric name for some of the St. Cassian species: we think he would be justified in even founding a new genus to receive them.

The plates that accompany this paper are admirable bits of drawing, but the figures would in most instances have been more satisfactory for working purposes had more of them been enlarged, and those that are enlarged yet further magnified. The double numeration of these plates is, moreover, both clumsy and unnecessary.

It is very interesting to observe in how many of the species of *Naticopsis* the colour markings seem to have been preserved, nor is this the less remarkable because instances of a similar description from yet older formations are on record.

(BV)[2].

NOTES.

SIR HENRY GILBERT sailed for America at the end of last week, to deliver the biennial Rothamsted Agricultural Lectures. There is an appropriateness in Sir Henry being the lecturer for 1893, the jubilee year of the Rothamsted wheat experiments. He is, of course, bound in the first place for Chicago, where Sir John Lawes and himself have a considerable exhibit.

WE are glad to learn that the fund which is being raised to pay the expenses incurred by Dr. Budge, of the British Museum, in the action recently decided against him, now amounts to about £900, so that there is every prospect of the whole amount being shortly obtained.

LORD KELVIN will open the new science buildings erected at the Leys School, Cambridge, on Saturday, October 28. The buildings include an extensive museum, three lecture theatres, and laboratories for elementary and advanced chemistry, biology, and physics.

THE Paris correspondent of the *Times* says that a collection of Egyptian papyri, recently purchased by subscription for the Geneva Public Library, is being examined by M. Jules Nicole. Among the discoveries already made are included a didactic elegy on the stars, and several scientific compositions.

THE Adelaide meeting of the Australasian Association for the Advancement of Science commenced on September 25, when Dr. Stirling, C.M.G., F.R.S., delivered a lecture on "Prehistoric Man." Prof. Ralph Tate, the president-elect, delivered the presidential address on the following day. The following are the sections and the names of their presidents:—Astronomy, mathematics, and physics, Mr. H. C. Russell, C.M.G., F.R.S.; chemistry, Mr. C. N. Blake; geology and mineralogy, Sir James Hector, K.C.M.G., F.R.S.; biology, Mr. C. W. de Vis; geography, Mr. A. C. Macdonald; anthropology, Rev. S. Ella; economic science and agriculture, Mr. H. C. L. Anderson; engineering and architecture, Mr. J. R. Scott; hygienic and sanitary science, Mr. A. Mault; mental science and education, Prof. Henry Larvire.

AN International Exposition will be inaugurated in San Francisco on January 1, and will remain open until June 3, 1894.

THERE is to be a "castle in the air" at the International Exhibition to be held at Antwerp next year. An immense balloon, built in six separate parts, on the principle of the water-tight compartments in steamers, will be held captive by means of ropes, and from it a castle-shaped structure, 33 yards long by 8 yards wide, will be suspended instead of a car. Entrance to the castle will be obtained by means of two lifts, and the supply of gas will be kept up by connecting a generator on the ground with the balloon by means of a silk tube.

THE Congress of the Photographic Society of Great Britain and Affiliated Societies was opened on Tuesday. In his presidential address, Captain Abney reviewed the advances recently made in photography, dwelling particularly upon the Lippmann processes for obtaining photographs in natural colours. A special lantern display will be held this evening at the Gallery of the Society in Pall Mall.

A TERRIBLE storm passed over the Gulf of Mexico on Monday, October 2, and, in conjunction with a tidal wave, did serious damage. Immense destruction was caused to the plantations, crops, and villages near the shore, and a report from New Orleans states that 1200 lives were lost in the portion of Louisiana visited by the cyclone. Hundreds of small vessels along the Gulf Coast were wrecked, and at Chandileur Island the wind is reported to have had a velocity of 100 miles an hour. All the buildings on the island, including the lighthouse, were destroyed, several miles of the island being completely washed away. As the railway and telegraph service in the region visited by the storm have been destroyed, details of the path traversed and the damage done have not yet been obtained.

THE *Société d'Encouragement pour l'Industrie Nationale* has made the following awards. The grand medal for agriculture to Prof. E. Lecouteux; the prize of 3000 francs for perfecting the ventilation of mines, to M. Murgues; the prize of 2000 francs for a study of the coefficients required in a calculation of the mechanical possibilities of an aerial machine has not been awarded, but a sum of 500 francs has been assigned to Prof. Le Dantee. The prize of 2000 francs for the inventor of new methods of utilising petroleum, advantageously and without danger, for industrial and domestic purposes, has also not been awarded, but an encouragement in the shape of 1000 francs has been given to Dr. Paquelin. M. Kayser has obtained the prize (3000 francs) for a study of alcoholic ferments, and M. Girard that of 2000 francs for the best experiments on cattle feeding. M. Decaux has received the prize of 1000 francs for a new photographic shutter. Gold medals have been awarded to MM. L. Figuier, J. Fournier, M. Mustel, E. Petrousson, and G. Tissandier (the Editor of *La Nature*).

THE Patent Laws of this country make no provision for an official search as regards the novelty of inventions, hence the necessity for a perfect system of indexing of specifications of patents can readily be understood. In order to facilitate reference and enable intending patentees to satisfy themselves whether their brain-creations are really novel or not, a new series of illustrated Abridgment Classes is being published at the Patent Office. These abridgments have been classified according to subject, and they refer to all the specifications of patents applied for in the period 1877–83. Everything depends, of course, upon the manner in which a classification of this character is made, and we are glad to be able to say that the Comptroller-General has grouped the specifications in an excellent manner. He certainly deserves the thanks of men of science for arranging philosophical instruments in a class by themselves. The volume devoted to this class includes over five hundred short illustrated descriptions of inventions relating to optical, nautical, surveying, mathematical, and meteorological instruments. It is interesting reading, and should be useful to devisers of apparatus for any branch of science. During the period covered by the summary, inventors appear to have directed their attention principally to perfecting and devising new forms of those instruments which were already in existence. At any rate, very few new discoveries are indicated by the inventions set forth, which may perhaps be taken as evidence that the fundamental laws of nature have now been fairly well recognised. Among the most ingenious apparatus we may note the telemeters, or range-finders, by means of which the distances of objects can be ascertained directly from a single station, the importance of which from a military or naval stand-point cannot be over-estimated. Other surveying instruments, such as theodolites, levels, telescopes, &c., are fully represented, as also are magnetic compasses, ships' logs and sounding apparatus, sextants, and other nautical instruments. In the field of meteorology we find barometers, thermometers, hygrometers, anemometers, wind vanes, sunshine recorders, &c., while among optical instruments occur improvements in telescopes and microscopes, stereoscopes, magic-lanterns, and spectacles, reading-glasses, lenses, and reflectors. The volume also comprises mathematical drawing instruments and tripod stands for various kinds of apparatus.

A large number of papers on various branches of anthropology were discussed at the International Congress of Anthropology, which met at Chicago from August 28 to September 2. Dr. D. G. Brinton opened the session with an address on "The Nation as an Element in Anthropology." The second day's meeting was devoted to Archæology, principally American. On the third day, devoted to Ethnology, Dr. Brinton read a paper "On the Alleged Evidences of Ancient Contact between America and other Continents," in which he categorically denied that "any language, art, religion, myth, institution, symbol, or physical peculiarity of the American aborigines could be traced to a foreign source." Folk-lore was the subject assigned to the fourth day's proceedings, Religions to the fifth, and Linguistics to the sixth. The meetings were well attended, and the presence of foreign delegates showed that the Congress was truly an international one.

At the Meteorological Congress held at Chicago in August last, as many as 130 papers were read "outlining the progress and summarising the present state of our knowledge of the subjects treated." In Section A, presided over by Prof. C. A. Scholt and Mr. H. H. Clayton, the papers were devoted to instruments and methods of observation, especially methods of observing in the upper air. Prof. Cleveland Abbe was chairman of Section B, which mostly dealt with questions of meteorological dynamics, much attention being also given to the study of thunderstorm phenomena in various countries. Section C, of which Prof. F. E. Nipher was chairman, comprised a series of sketches of the climate of different portions of the globe. Section D, in charge of Major H. H. C. Dunwoody, was devoted to the discussion of the relation of the various climatic elements to plant and animal life. Section E, under Lieut. W. H. Beehler, dealt with questions relating to marine meteorology, particularly to ocean storms and their prediction, methods of observation at sea, and international co-operation. Prof. Charles Carpmael and Mr. A. Lawrence Rotch presided over Section F, which comprised papers relating to the improvement of weather services, and especially to the progress of weather forecasting. Prof. F. H. Bigelow guided Section G, which dealt with problems of atmospheric electricity and terrestrial magnetism and their cosmical relations. Section H (Prof. Thomas Russell) had to do with rivers and the prediction of floods. Section I, under Oliver L. Fassig, was devoted to historical papers and to bibliography, with special reference to the history of meteorology in the United States. Preparations have been made for printing all the papers, and it is hoped that the work will be completed at an early date.

The weather over our islands has recently been much disturbed by the passage of atmospheric depressions across the country; rainfall has been general in all parts, while thunder and lightning have frequently occurred, especially over the western and southern parts of the kingdom. On Sunday, the 8th inst., three-quarters of an inch of rain fell in the north of Scotland, and on the following day a depression in the south caused a heavy downpour in that part of the country; the fall measured in the neighbourhood of London on Tuesday morning amounted to an inch and a quarter. The excess above the average in all the western and southern parts of England during the week ended the 7th inst. was very large, amounting to an inch in the south-western district. The greatest deficiency in the aggregate amount since the beginning of the year was then 8·7 inches in the west of Scotland, while in the south of Ireland, and the midland counties of England, the deficiency exceeded 6 inches.

We have received a copy of the *Osservazioni meteorologiche* made in the year 1892 at the Turin Observatory, containing observations taken three times daily, with daily and monthly means, and the differences from the normal values, calculated by Dr. G. B. Rizzo, assistant at the Observatory. We are indebted to the Italians for some of the earliest and best series of observations; those for Bologna began as early as 1723, and M. Toaldo, the first director of the Padua Observatory, early established a system of more than sixty stations, the results of which were published by M. Schouw, in Copenhagen, in 1839. At the Turin Observatory observations were begun in 1753 (see Nature, June 1, 1893, p. 108), and for many years past the results have been regularly published each year. The cost of the establishment is now borne partly by the University, and partly by the town of Turin.

Forest-Inspector R. Schütte reprints, from the *Agricultural Journal* for West Prussia, an elaborate account of the district known as the Tucheler Haide, the largest continuous forest district of Western Prussia, extending over an area of thirty-five square miles. It is characterised by great and sudden changes of temperature. The winter minimum generally falls below −20° R. Snow has fallen on May 19, followed by a temperature of 21° R. on the 26th, and this again by night frosts on the first and third of June. Prehistoric remains are found belonging to the later stone and to the bronze ages. The inhabitants are occupied almost entirely with forestry and agriculture. Polish is still the prevalent language, though German is now generally understood.

Although one of the most recent organisations of its kind, the Geological Survey of Russia has already taken high rank amongst the surveys of Europe; the director is A. Karpinsky. The survey was commenced in 1882, and has published thirteen 4to volumes of Memoirs and eleven 8vo volumes of Bulletins. The maps, on the scale of 1 : 420,000, are issued with the Memoirs. An additional annual publication is the Bibliography of Russian Geology from 1885 onwards, which is edited by S. Nikitin. This gives abstracts in Russian and French of all publications relating to the geology of Russia. Although the detailed survey of this vast country is not yet sufficiently advanced for the publication of all the large scale maps, the surveyors have now accumulated enough material to warrant the issue of a general map on the scale of 1 : 2,520,000. This has recently appeared in six sheets, with brief explanatory text in two editions—Russian and French. (On the title-page of the French edition the scale of the map is erroneously given as 1 : 520,000.) Fuller explanations of various districts and formations will be issued subsequently. Some of the information here published was supplied by S. Nikitin for the geological map of Europe issued by Prof. Prestwich in vol. ii. of his "Geology." The map now issued is a beautiful example of cartography; it is not overloaded with detail, but the streams, railways, and main roads are clearly indicated. The names of places, rivers, &c., are printed in Russian, but to the descriptions of geological formations in the index a translation in French is added. The following statement of subdivisions indicated on the map will give some idea of the amount of geological information supplied:—5 Quaternary, 5 Tertiary, 2 Cretaceous, 1 Volgian, 3 Jurassic, 4 Triassic, 1 Permian, 1 Permo-Carboniferous, 2 Carboniferous, 5 Devonian, 2 Silurian, 1 Cambrian, 1 Crystalline Schists, 1 Gneiss, Granite, &c., 5 Volcanic Rocks, Tuffs and Serpentine. In addition to these well-recognised rock-groups extra tablets and colours are given for beds between the Permian and Trias occurring in some districts and not yet understood; the Devonian and Carboniferous, not separated, of the Transcaucasus; the Palæozoic rock, of the Caucasus; and for the ancient sandstones, &c., of Volhynie. The interesting group of Volgian beds, linking together the Cretaceous and Jurassic, are developed around Moscow, in Simbirsk and Kalouga; they have recently been discovered in

Poland. The system of colouring adopted is, as far as possible, that of the International Geological Map of Europe. The quaternary deposits are omitted where they would much obscure the solid geology, but elsewhere they are shown. In some parts, especially in Northern Russia, these superficial deposits are thick and widely spread, so that the solid geology is not known; here it was necessary to show only these deposits. The southern limit of erratic blocks is shown by a strong red line.

Messrs. Fletcher, Russell, and Co., the well-known makers of gas appliances, have just introduced a new process to supersede the use of Berlin black and black-lead for protecting the cast-iron portions of their manufacture. The casting is coated with a film of enamel, which is so thin that even the finest details on the metal are preserved. This enamel is said to be absolutely proof against rust, and preserves its qualities at any temperature up to a bright red heat. All colours are obtainable, including gold and silver, bright or dull, and as many as are wished can be produced on one casting. The process therefore offers great facilities for decorative work of all kinds, and its protective qualities should ensure it a wide field of usefulness.

In a previous number of Nature (No. 1247) we published the opening address by Mr. Jeremiah Head, President of Section G, Mechanical Science. In this, among many of the mechanical forces used by man, he referred at some length to the prospect of man ever being capable of flying. Some very interesting experiments, to which no allusion was made, although not bearing directly on actual flight, may yet be found of sufficient importance to be here related. For a very detailed account the reader may be referred to No. 205 of the weekly journal, *Prometheus*. The experimenter in question is Herr Otto Lilienthal, and his success in his so-called "flight" is the result of much thought and considerable practice. The apparatus may be described as a pair of large wings, similar in principle and construction to those of a bird, with two tails at the back, one placed vertically, and the other horizontally. The wings are rigid and fixed, and no motive power at all is used; the whole apparatus weighs twenty kilograms. At the place where the experiments have been carried on, a long sloping hill has been used, with a platform raised about ten metres above the general surface at the top, for the starting point. From this platform the experimenter grips the apparatus between the wings or sails with his hands, and springs off the edge. In the flight he descends at an angle of about 10° to 15°, and the distance covered is sometimes very considerable. In the experiments carried on between Rathenow and Neustadt he covered 80 metres, while from another point he made a flight of 250 metres. The wind of course plays an important part in these flights, but Herr Lilienthal says that with practice one can steer the apparatus well. With the wind blowing stronger on one wing than on the other the equilibrium of the apparatus was found to be greatly disturbed, but this was checked by the movement of the legs, which changed the position of the centre of gravity. In these experiments there is a great opportunity for gaining experience in steering, and it seems very likely that we may learn much thereby.

The assumption, current some years ago, that the properties of liquids change in proportion to the amount of matter held in solution, has already been invalidated for the case of electrolytic conductivity. Messrs. F. Kohlrausch and W. Hallwachs, in *Wiedemann's Annalen*, publish some results showing that the assumption is also erroneous in the case of density of dilute aqueous solutions. The method adopted was the Archimedian one of immersing a solid in the solution and noting its decrease in weight. Errors due to capillarity were eliminated by attaching the solid, a glass ball, to the suspending wire by means of a clean cocoon fibre. During mixing and stirring, the glass was held in position by glass rings. The stirrer was one of mica or platinum. Densities were observed up to 1·03, and the weighings were reliable to within 0·2 mgr. provided that no dust or fibres were attached to the cocoon thread. This gave a limit of error equal to 1 in 10,000. Large variations of temperature were corrected by a flame or ice, smaller ones by calculation according to known formulæ. All the bodies investigated show a decrease of the ratio of condensation to concentration between 0·005 and 0·5 gramme-equivalents per litre. This decrease amounts to 1 per cent. for sugar, 2 for hydrochloric acid, 2·5 for common salt, 13 for phosphoric acid, and 20 or sulphuric acid. The correspondence between this change of density and the change of electrolytic conductivity is very apparent. Sugar, a non-electrolyte, shows the greatest constancy of molecular density in solution. The authors intend shortly to publish analogous results obtained in their investigation of optical refraction.

M. Van Aubel has continued his experiments on the resistance of bismuth, and gives an account of the results he has obtained in the *Journal de Physique* for September. The results obtained are of special interest, as the use of spirals of bismuth seems to be the most convenient way of measuring powerful magnetic fields, at any rate with a sufficient degree of accuracy for most industrial purposes. According to Righi, the electrical resistance of commercial bismuth at 0° varies considerably, and bismuth which has been compressed has its resistance less affected by magnetism than that which has been melted. The author in his experiments has made use of pure bismuth, prepared by electrolysis according to the method he gave in his former paper in the *Annales de Chimie et de Physique*, and his observations show that neither sudden cooling nor compression has much effect on the electrical properties of pure bismuth. The resistance at 0° C. and the rate of change of the resistance with temperature, and the strength of the magnetic field in which it is placed, are almost the same, for rods that have been annealed quickly cooled, or compressed. The resistance always increases with rise of temperature, and between 0° and 100° the change is very nearly regular. A mere trace of impurity, however, completely changes the properties of the metal. The action of a magnetic field being the same, whatever the mode of preparation of the bismuth, it is better to use the spirals of compressed bismuth rather than the more difficultly obtained films of electrolytically deposited metal used by M. Leduc.

In the current number of the *Philosophical Magazine*, Mr. John Trowbridge has a paper on the oscillations of lightning discharges and of the aurora borealis. By means of a rotating mirror the author has photographed the oscillating spark passing between two knobs, using both great electromotive force and great quantity of electricity. He finds that the subsequent sparks, at any rate for three hundred-thousandths of a second, exactly follow every sinuosity in the path taken by the pilot spark. Thus the comparatively small resistance to the passage of a second spark in air is probably due to this permanence of path.

The University Correspondence College Press has issued the London University Guide for the year 1893–94.

Bulletins 96–99 have been received from the Michigan Agricultural Experiment Station.

Mr. G. Gammie has prepared a report on his botanical tour made on the Sikkim-Tibet frontier during 1892. The report is issued by the Superintendent of the Royal Botanical Gardens, Calcutta.

We have received the second part of "A Dictionary of Birds," by Prof. A. Newton and Dr. Gadow, extending from "Ga" to "Moa." Messrs. A. and C. Black are the publishers.

MR. W. F. PETTERD has issued, through Mr. Wm. Grahame, Jun., Hobart, a catalogue of the minerals known to occur in Tasmania, with notes on their distribution.

WE have received reports containing the results of physical and meteorological observations made on the coast of Germany during the first half of 1892. The reports are published by Herr Paul Parey, Berlin.

THE last ordinary meeting of the session of the North of England Institute of Technical Brewing will take place in Manchester on October 20, when Prof. Percy Frankland, F.R.S., will read a paper on "The Polariscope in relation to Chemical Constitution."

THE Upper Norwood Literary and Scientific Society has prepared a varied programme of lectures for the coming session, in which science and literature are given equal prominence, and are treated by well-known lecturers.

A MEMOIR, by Dr. Carlos Berg, the Director of the National Museum at Buenos Ayres, on *Geotria macrostoma* (Burm.), Berg, and *Thalassophyrne Montevidensis*, Berg, has been reprinted from the *Anales del Museo de la Plata*.

THE second part of "Dissections Illustrated," by Mr. C. Gordon Brodie, has been published by Messrs. Whittaker and Co. It refers to the lower limb, and includes twenty finely-drawn coloured plates and six diagrams, by Mr. Percy Highley.

MESSRS. O. NEWMANN AND CO. are publishing a series of 120 new wall diagrams for instruction in botany and zoology in schools and colleges. The diagrams are well printed in colours on a black ground, and are highly commended by German educationalists.

THE thirteenth edition of Gray's "Anatomy, Descriptive and Surgical," edited by Mr. T. Pickering Pick, has been published by Messrs. Longmans, Green and Co. The work has been thoroughly revised, and in some parts rearranged, and much new matter referring to surgical anatomy has been added.

THE first number of a bright little quarterly magazine, *The Nature Lover*, edited by Mr. H. Durrant, has just been published by Mr. Elliot Stock. In style it is like the Selborne Society's magazine, *Nature Notes*, though in rather lighter vein. We trust that the lovers of nature are numerous enough to make the venture a success.

DR. V. STERKI has made an exhaustive study of those minute and interesting molluscs which are generally regarded as constituting the genus *Vallonia*. His paper appears in the Proceedings of the Academy of National Sciences of Philadelphia, 1893 (pp. 234–279), and though not a monograph of the genus, it will serve as a useful guide to further investigations.

THE Proceedings of the Liverpool Geological Society (part 1, vol. vii.) contains several interesting papers communicated during the thirty-fourth session (1892–93). Among these may be mentioned the address of the president, Mr. W. Hewitt, on "The Physical Conditions of the Aralo-Caspian Region, as bearing on the conditions under which the Triassic rocks were formed," and a paper on "The Formation of Clay," by P. Holland and G. Dickson.

A LECTURE on "Bulbous Irises," delivered before the Royal Horticultural Society in May, 1892, by Prof. Michael Foster, has been expanded, and is now published separately at the society's offices. A detailed description of the various species mentioned in the lectures has also been added. Growers of irises will find the book of great use to them, it being intended more for the gardener than the botanist.

A MONOGRAPH of the "Coraciidæ, or Family of the Rollers," by Mr. Henry E. Dresser, will shortly be published by subscription. This work will contain illustrations, accompanied by letter-press, giving as complete an account as possible of all the known species of these richly-coloured birds. All the species have been drawn, life-size, on stone, by Mr. J. G. Keulemans.

THE Rev. W. Colenso, F.R.S., read several interesting botanical papers before the Hawke's Bay Philosophical Institute during 1892, and they are published in the Transactions of the New Zealand Institute, vol. xxv. A paper of much interest, entitled "Bush Jottings," is a brightly-written account of many botanical sights to be seen in the high inland wooded district known as "the bush." More technical in their character are the descriptions of a few newly-discovered rare indigenous ferns, some phanerogamic plants, and a list of fungi. All these contributions help to make known the botany of New Zealand.

WE have received from Mr. Stanford an "Illustrated Official Handbook of the Cape and South Africa," which reflects the greatest credit upon all who have had anything to do with its production. The volume is edited by John Noble, who evidently recognises the importance of science, for we find chapters devoted to the following subjects:—"Geology, Fossils and Minerals of South Africa," "Vertebrate Fauna of South Africa," "Flora of South Africa," "Woods and Forests," and "Viticulture," all of which are contributed by specialists, who, as far as we can see, have performed their several tasks with great care. The work is enriched with a map and over a hundred "process" illustrations.

SILICIDE of carbon, CSi, has been obtained by M. Moissan in beautiful large crystals very similar in appearance to sapphires and considerably harder than rubies, by four different processes involving the use of his recently described electric furnace. The existence of this curious compound of two closely allied elements was first pointed out by M. Colson, who obtained it in the amorphous form by heating crystals of silicon in a current of hydrogen charged with vapour of benzene. Some years ago M. Moissan obtained it, in the condition of crystals several millimetres in length, by dissolving carbon in silicon, the latter being maintained in a state of fusion by means of a small but powerful blast furnace. The crystals were isolated from the excess of silicon by treating the product with a boiling mixture of nitric and hydrofluoric acid. M. Moissan now shows, however, that crystallised silicide of carbon may be much more readily prepared by heating a mixture of carbon and silicon, in the proportions of their atomic weights, in the electric furnace. The mass of crystals produced during the passage of the current may be purified by boiling first in the acid mixture above mentioned, and subsequently in an oxidising mixture of nitric acid and potassium chlorate. The crystals produced by this simple method are most frequently yellow, but are quite transparent if the operation is performed rapidly in a closed crucible of carbon, and provided the silicon employed is free from iron. Sometimes, however, the crystals are coloured blue, and closely resemble sapphires. The second process for the preparation of the compound consists in heating in the electric furnace a mixture of iron silicon and carbon, or more simply of iron silica and carbon; a regulus of metallic iron containing large crystals of silicide of carbon is produced. The third process consists in reducing silica by means of carbon in the crucible of the electric furnace, and this mode of preparation possesses the advantage of furnishing crystals which are more nearly colourless than those produced by the first two methods, inasmuch as the silica and carbon can be employed in a fairly pure state. Perhaps the most interesting of all the methods of preparation is the fourth, in which the compound is formed by direct synthesis by the union of vapour of carbon with vapour of silicon. For, as has been previously described in these columns, M. Moissan is able to actually distil carbon at the high temperature of the arc which he is able to produce in his furnace. The experiment is conducted in a small crucible of pure carbon of elongated form, and enclosing a little block of silicon. The base of the crucible is arranged so as to occupy the position where the highest temperature of the arc is attained, and after the conclusion of the experiment the interior of the crucible is found to be covered with almost colourless prismatic needles of carbon silicide.

CRYSTALLISED carbon silicide is an extremely stable substance which resists the action of the most energetic reagents, even those which are capable of readily attacking its elementary constituents. The pure crystals are colourless and perfectly transparent, and present the appearance of regular hexagons. Their density is 3·12, and they are so hard that the ruby is readily scratched, and may be ground by means of the powdered compound. They are unalterable in air or sulphur vapour at 1000°. Chlorine attacks them very slowly at 600°, but more rapidly at 1200°. Fused nitre and potassium chlorate are entirely without action upon them, as are likewise boiling sulphuric, hydrochloric, and nitric acids, and even aqua regia and the silicon-dissolving mixture of nitric and hydrofluoric acids are incapable of attacking them. Fused caustic potash, however, after heating to redness for an hour in contact with them, reacts with formation of carbonate and silicate of potassium, and thus affords a means of estimating the content of silicon. The carbon may also be estimated by repeated combustion with chromate of lead, which gradually effects oxidation of the carbon. The analyses thus carried out agree in all cases with the simple formula CSi.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include various types of *Foraminifera*, colonies of the Hydroid *Coryne pusilla* (without gonophores), a colony of the *Scyphistoma* stage of *Aurelia*, and the Nudibranchs *Platydoris planata*, *Candiella plebeia* and *Polycera quadrilineata*. In the floating fauna the Hydroid medusæ *Cytæandra areolata* and *Eutima insignis* have been observed in addition to the forms mentioned last week.

THE additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus*) from West Africa, presented by Mr. Swaniston Cyril Hopkins; a Serval (*Felis serval*), a Nilotic Crocodile (*Crocodilus vulgaris*) from Africa, presented by Mr. T. E. C. Remington; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Mrs. Noakes; a Yellow-collared Parrakeet (*Platycercus semitorquatus*) from Australia, presented by Miss A. Fenwick; a Common Sheldrake (*Tadorna vulpanser*) European, presented by the Rev. H. G. Morse; an Oyster-catcher (*Hæmatopus ostralegus*) European, presented by Mr. Edmund Elliot; a Goliath Beetle, from West Africa, presented by Mr. F. W. Marshall; two Great Eagle Owls (*Bubo maximus*) European, deposited; a Flocky Lemur (*Avahis laniger*) from Madagascar, a Raccoon-like Dog (*Canis procynides*) from North-east Asia, a Sanderling (*Calidris arenaria*), a Puffin (*Fratercula arctica*) European, purchased.

OUR ASTRONOMICAL COLUMN.

ASTRONOMY AT THE WORLD'S FAIR.—The astronomical exhibits at Chicago seem to be fairly representative of the state of astronomical science at the present day, but they are too much scattered about in the different buildings for a proper study of them to be made. Among many of the more interesting exhibits we may mention the following: Fine collection of astronomical photographs, made by the Harvard College Observatory, which included those of stellar spectra nebulæ and clusters, and of a portion of the lunar surface enlarged over one thousand diameters. Dr. Chandler's four-inch almacantar, the collections of Draper and Langley, and the diffraction gratings and photographs of spectra by Prof. Rowland, the last of which formed the Johns Hopkins University exhibit. Specimens of the famous Jena optical glass, Kirchhoff's original spectroscope, Brill's mathematical models, and the magnetic apparatus of Gauss and Weber form part of the German Educational exhibit. In the English exhibit are found many astronomical photographs by Roberts, Gill, and others; others from the Royal Observatory, Greenwich, Boeddicker's Milky Way drawings, and the fine five-foot glass speculum by Dr. Common. Among some of the exhibits of the American astronomical instrument makers, we are glad to note the mounting of the great forty-inch Yerkes telescope by Warner and Swasey, who exhibit also some minor instruments. J. A. Brashear exhibits the stellar spectroscope for the Yerkes telescope, eighteen-inch and fifteen-inch objectives, gratings, &c. Among G. N. Saegmuller's (of Washington) exhibits is a four-inch steel meridian circle. Two twenty-three-inch discs of the celebrated Jena glass are shown by Schott and Genossen, of Jena, in addition to other specimens of optical glass. In the Cape Colony exhibit Dr. Gill's interesting stellar photographs are prominent, while the Lick Observatory display is housed in the educational department of the California State building, and, as *Science* says, is "strangely enough mixed up with the Kindergarten exhibit there." The U.S. Government building contains interesting apparatus as used in the Coast Survey, while the Naval Observatory shows a small observatory with several instruments.

THE AURORA OF JULY 15, 1893.—The system of observation of the aurora as lately instituted, seems to be already at work, and the observations of the aurora of July 15, most of which have been made on this system, show that the results are of the highest interest. A brief account of this aurora, by M. A. Veeder, will be found in the *Bulletin of the New England Weather Service* for the month of August (No. 18), from which we gather the following few notes:—With regard to the places of visibility and invisibility, it may be mentioned that its absence was verified up to midnight in Nova Scotia. In New England it was observed at a few stations, of short duration, and not at all conspicuous. Towards New York it was a fine display, and lasted all night, and was seen as far south as Washington at this longitude, while it was defined as a fine red aurora at Salt Lake city, and was seen as far south as the Lick Observatory, at both of which places this phenomenon is very rare. A special feature of this aurora was the "formation of a narrow band having an east and west direction, and passing just south of the zenith." This was seen in New England, the neighbourhood of Lake Ontario, and occasionally in Michigan, Wisconsin, and Iowa. An unusual formation recorded was that of an auroral curtain with a clearly defined lower margin. The twenty-seventh day interval coinciding thus with a synodic revolution of the sun, shows, as M. Veeder says, that whatever it is in the sun that originates an aurora can have this effect only when it has reached a certain position relative to the earth, and, further, that "the effect must proceed from the eastern limb." That in certain cases of large sunspots auroral effects might proceed from the central meridian of the sun as seen from the earth, M. Veeder freely admits; but he adds that, until further study has been made, this question cannot as yet be said to be satisfactorily answered.

NEW VARIABLE STARS IN CYGNUS.—A communication to the *Astronomischen Nachrichten*, No. 3191, by Herr Fr. Deichmüller, informs us of two new variable stars in the constellation of Cygnus. Their positions are respectively

$$\left.\begin{array}{rrrl} \text{h.} & \text{m.} & \text{s.} & \quad\;\; ^\circ \quad\; ' \\ 19 & 8 & 27 & +\ 49\ 24{\cdot}2 \\ 20 & 6 & 24 & +\ 47\ 23{\cdot}0 \end{array}\right\} 1855$$

The first of these stars has a range of one and a half magnitudes, while the second varies from $7\frac{1}{2}$ to the ninth magnitude.

ASTRONOMICAL WORKS (ANTIQ.).—We have received the catalogue of Herr Oswald Weigel's Antiquarium in Leipsig, which is devoted simply to works on astronomy (astronomical geography and geodecy). Included also is the library of Prof. C. Fearnley, of Christiania; so that our readers may be sure that there are now some important works for sale.

GEOGRAPHICAL NOTES.

NORWEGIAN enterprise has led to the fitting-out of a steamer, renamed the *Antarctic*, for a whaling voyage to the Antarctic Sea south of New Zealand, where Ross attained his highest south latitude in 1842. The *Antarctic* has already sailed, but will touch at an Australian port to complete preparations. It is understood that those on board will endeavour to make as complete meteorological observations as possible throughout the voyage.

A TELEGRAM from San Francisco, dated October 3, states that the American steam-whaler *Newport*, one of the fleet working north of the Arctic coast of America, which passed last winter at Herschell Island (long. 139° W. near the mouth of the Mackenzie), succeeded this summer in steaming through an almost open sea to 84° N. No details are given, and until the observations for latitude have been critically examined it is necessary to reserve an opinion as to the latitude really attained. The farthest north points, reached through Smith Sound, are 83° 20′ by Markham, and 83° 24′ by Lockwood. If the report is correct, the *Newport* got nearly fifty miles farther north than any previous expedition.

MR. F. G. JACKSON, who is travelling in the Yalmal peninsula, reports that Dr. Nansen did not finally leave Yugor Strait until August 20, the ice in the Kara Sea turning out to be much worse than was expected. The conditions must have improved shortly afterwards, however, as a telegram from St. Petersburg announces the safe arrival in the Yenesei of the Russian vessels which left Dumbarton with railway material on July 29. The date of arrival is not mentioned, but the fact proves that the *Fram* would have no difficulty in getting east as far as the Yenesei, at any rate, and as she is not reported by the Russian vessels, she was probably far beyond that river before they arrived.

PROF. KOTO publishes in the *Journal of the College of Science*, Imperial University, Japan, a detailed description of the surface changes accompanying the great earthquake of 1891, illustrated by sketch maps and photographic views of the great fault, forty miles long, which was formed in the valley of Neo. On one side of this fault the ground has subsided in places for nearly twenty feet, and has also been displaced horizontally. The result, apart from the destruction of towns and buildings, has been to considerably modify the physical geography of an extensive area, changing the course of streams and their rate of flow, forming swamps, and in many ways accelerating the gentler processes of surface change by erosion.

MR. CLEMENTS R. MARKHAM, President of the Royal Geographical Society, has this year been invited to deliver the opening lecture at the three provincial Geographical Societies. He opened the session of the Tyneside Geographical Society at Newcastle, by a lecture on Peru, on the 6th; that of the Liverpool Geographical Society, by an address on the Polar Regions, on the 10th; and that of the Manchester Geographical Society on the 11th, when his subject was Central Asia with special reference to trade routes. The interest taken in the younger societies by the Royal Geographical Society is sure to increase their popularity and usefulness in their own localties.

BIOLOGY AT THE BRITISH ASSOCIATION.

ON Thursday the address of the President was for several reasons postponed till 12.30, and the work of the section was opened by the Chairman (Sir William Flower) with a sympathetic reference to the recent sudden death of Mr. George Brook, who was to have been one of the secretaries at this meeting. A paper was then read by Dr. David Sharp, on the zoology of the Sandwich Islands. This was followed by the report of Prof. Newton's committee on the present state of our knowledge of the zoology of the Sandwich Islands. The committee have obtained valuable results in several departments of zoology, and more especially in entomology. The consignments received during the year from their collector may be roughly estimated at nearly 150 birds'-skins, 3000 insects, 1000 shells, a collection of spiders in spirit, together with some crustaceans, worms and myriapods. The importance and urgency of the work carried on was testified to by Sir William Flower, Prof. Newton, Dr. Hickson, and others. The report of the committee dealing with observations on the migrations of birds at lighthouses was then read by Prof. Newton. This committee have made progress with the systematic tabulation of their statistics, and are now commencing to fill up the schedules for their final report. The sixth report of the committee investigating the zoology and botany of the West India Islands shows that the Committee have been chiefly engaged during the past year in working out the great series of specimens secured from the West Indian region by means of the collectors. Papers on the birds, on the myriapods, scorpions, pedipalpi, peripatus, and the parasitic hymenoptera, have been published, and investigations on other groups of insects are now proceeding. Collections of various groups of cryptogams have also been made, are now being worked out, and are proving to comprise many new species. The committee propose to examine next the island of Margarita, the natural history of which is wholly unexplored. An important note on the discovery of *Diprotodon* remains in Australia, by Prof. Stirling, was read by Prof. Newton. The new material now found has added to our knowledge of the structure of this remarkable gigantic marsupial, especially in regard to its limbs and feet.

The presidential address (*see* NATURE, p. 490), in the absence of Canon Tristram from illness, was read in the afternoon by Sir William Flower; and the vote of thanks was proposed by Prof. Newton and Prof. Burdon Sanderson.

The section opened on Friday with a physiological discussion on the physico-chemical and vitalistic theories of life. The discussion was opened by Dr. J. S. Haldane, of Oxford, who, starting from the fact that about the middle of the century physical and chemical theories to explain the peculiar properties of living organisms were completely substituted for the traditional vitalistic theories, proceeded to inquire how far this substitution has been justified by the results of subsequent investigation. He argued that as evidence has accumulated the failure has become more and more manifest of the attempts to specify physical and chemical factors from which vital properties may be deduced. This argument he based on the facts relating to cell-formation, nutrition, heat-production, the secretion and absorption of solids, liquids, and gases, and to other physiological processes. He then endeavoured to show that the old vitalistic theories were not mere expressions of the negative fact that physiologists are face to face with a large residuum of unexplained facts, but constituted real working hypotheses, which summarised the peculiarities of living organisms, and indicated fruitful lines of inquiry. In conclusion he maintained that the former crude beliefs as to the existence of a material or immaterial "vital principle," formed no essential part of a vitalistic theory of life.

The Chairman (Mr. Langley), in inviting discussion, said that the problems of life had been thought to be physical and chemical questions, and the mistake had been that they had been thought to be easy questions. Possibly the fact was that the unexplained residue appertained to more complex chemistry and physics than we know at present.

Prof. Cleland said that the old vitalism was dead, but that there was a new vitalism which must be supported. To him there appeared to be something in life in addition to the mere laws of dead matter.

Prof. Burdon Sanderson said that the real change that took place about 1840 was not a change of doctrine but a change of method. It was then seen that the only way to investigate the phenomena of life was by processes which they understood, such as those of chemistry and physics. A great number of easy questions had since been settled, and the difficult ones appeared now all the greater because we had come nearer to them. Profs. Schäfer, Allen, Heger, Hartog, Bohr, and Dr. Waller also took part in the discussion. In his reply Dr. Haldane maintained that physiologists had always employed methods of observation based on physics and chemistry. The change at the middle of the century seemed to him to be a change in working hypotheses rather than in methods.

The Chairman, in closing the discussion, said that during the first half of the century there had been a lamentable absence of results, mainly owing to the fact that the whole process of research was governed by the vitalistic theory.

A paper by Dr. A. R. Wallace, on malformation from prenata influence on the mother, was illustrated by photographs of a remarkable case of a child born with an imperfect arm some months after the mother had been engaged in dressing the wound of a gamekeeper who had had his arm amputated.

In the afternoon the section divided into the two departments of Physiology and Zoology. In the former, the following papers were read:—(1) On the digestive ferments of a large Protozoon, by Prof. Marcus Hartog and Augustus E. Dixon. The authors experimented with about 2000 large individuals of *Pelomyxa palustris*, and found that the watery extract hydrolyses starch paste in a neutral solution, and converts the starch rapidly into erythro-dextrin, has no action on thymolised milk in two days, liquefies fibrin rapidly in presence of dilute acids, only attacks fibrin very slowly and partially in neutral solution, and indol and skatol are not formed. (2) On the effect of the stimulation of the vagus on disengagement of gases in the swim-bladder of fishes, by Dr. Christian Bohr (Copenhagen). This showed that the air secreted in the bladder is largely composed of oxygen. The paper was illustrated by tables showing the increase in the proportion of oxygen at stated times during the refilling of the bladder after puncture. (3) On a method of recording the heart sounds, by Prof. W. Einthoven. (4) On nerve stimulation, by Prof. F. Gotch. The author finds that with the induction current he obtained excitation of the nerve of a frog at a low temperature which disappeared at a higher temperature, while with the discharge of a condenser the result was the reverse of that. He also found a similar difference in action in regard to the passage of the impulse down the nerve in the two cases. Therefore he comes to the conclusion that the impulse started in the nerve is somewhat different in the two cases. (5) On fatigue of nerves, by Prof. Schäfer. (6) On Calorimetry, by Dr. A. Waller. This applied more particularly to the temperature difference of the body under varying conditions of the surrounding medium. (7) The report of the committee on the physiological action of the inhalation of oxygen in asphyxia. The results are as follows:—(1) In the case of asphyxiated rabbits, oxygen is of no greater service than air; (2) pure oxygen when inhaled by a healthy man for five minutes produces no effect on the respiration or pulse; (3) oxygen produces no effect upon a patient suffering from cardiac dyspnœa, either on respiration or on pulse; (4) an animal can be kept for a long time in a chamber containing 50 per cent. of carbonic acid without muscular collapse, provided a gentle strea n of air or oxygen be allowed to play upon the nostrils.

In the Zoological Department the following papers were read:—(1) Report of the committee appointed to explore the region of the Irish Sea lying around the Isle of Man. The committee have conducted eight dredging expeditions, most of them lasting for several days; about 1,000 species of marine animals have been collected and identified, of these thirty-eight are new records to the British fauna, 224 are new to the district, and seventeen are new to science. Prof. Herdman gave a general account of the expeditions and the results attained, while Mr. A. O. Walker, Mr. I. C. Thompson, Mr. Stebbing, and Prof. Brady gave more detailed accounts of special groups of Crustacea. (2) Report of the committee on a deep-sea townet. (3) On luminous organs in Cephalopoda, by W. E. Hoyle. These minute light-producing organs are scattered over the general integument in certain species. (4) On the origin of organic colour, by F. T. Mott. This was to show that the colours in going from stem to blossom indicate a decrease in the amount of light absorbed, and the author contends that the amount of reflected light increases as the plant attains maturity. (5) On the roots of *Lemna*, and the reversing of the fronds in *Lemna minor*, by Miss Nina F. Layard, who showed that in dry seasons, when the fronds dried up, the root-cap would act as a protector for the tender cells of the root. Miss Layard accounted for the observed reversal of the fronds as cases where a growth had covered the upper surface, and the fronds had revolved in order to expose a better surface to the air.

The section met on Saturday forenoon, when the following papers, chiefly botanical, were taken:—(1) Report of the committee on the legislative protection of wild birds' eggs. This was read by Dr. Vachell, and supported by Prof. Newton, who urged the necessity of making known to the schoolboy which birds' eggs ought to be protected. (2) On the ætiology and life-history of some vegetal galls and their inhabitants, by C. B. Rothera. The author traced out the life-history of certain typical galls, those of *Cynips kollari*, *Teras terminalis*, and *Biorhiza aptera* being specially dealt with. He gave a series of facts positive and negative, which point to the action of the embryo, and not to the deposit of a special virus by the parent *Cynips*, as the direct and necessary agent in the production of the gall. He therefore discards the hypothesis of a specific virus deposited by the parent, and attributes the genesis and metamorphoses of the gall to the activities of the living embryos combined with the normal forces of the plant. (3) Report of the Committee on the Botanical Laboratory at Peradeniya, Ceylon, where a good deal of the apparatus requires to be renewed. (4) On some new features of nuclear division, by Prof. J. B. Farmer. This paper, illustrated by microphotographs, included some new results of researches on the centrogomes and the behaviour of the achromatic spindle. (5) Variations of fecundity in *Trifolium pratense* and its varieties, and *Trifolium medium*, by W. Wilson. This paper detailed some observations made as to varieties of clover, contrasting them with hybrids as regards fertility. (6) Lime salts in relation to some physiological processes in the plant, by Dr. J. Clark. The action of lime salts may modify the effect of low temperatures in seed germination. The author had succeeded in finding a *Bacillus* which is capable of breaking up the calcium oxalate, which is at one time precipitated in the plant. (7) On the cortex of *Tmesipteris tannensis*, by R. J. Harvey Gibson. This gives an account of the histology of the cortex of the stem, with special reference to the origin and nature of the "brown deposit" seen in the cells.

On Monday a joint meeting with Section C was arranged, when a discussion on "Coral Reefs" was opened by Prof. W. J. Sollas, F.R.S.

Prof. Sollas said that the problem before the Sections was to explain the presence of large groups of atolls in the deep ocean, every atoll in some of the groups, save for the land piled up by the breakers, rising just up to the level of the sea. The two fundamental difficulties which had to be met were the existence of a submarine bank and the presence of a lagoon, which sometimes attained a depth of 60 fathoms or more. Volcanoes had once been supposed to furnish by their cones the bank, and by their craters the lagoons. Possibly some individual atolls might be explained in this way, but not whole groups. Chamisso, postulating a submarine bank, accounted for the lagoon by the fact that corals grow fastest in the wash of the surf. In this way a lagoon 9 or 10 fathoms in depth might be formed, and some of the Florida reefs might be so explained. Dr. Murray accounted for submarine banks by the precipitation of organic sediment on volcanic cones, and for the lagoon by an explanation similar to Chamisso's, which he supplemented by supposing that the central part of the shoal was removed by solution. There was, however, no evidence that lagoons were deepened by solution, and much opposed to it. Deposition, and not solution, occurred in the lagoon, and so long as an atoll remained stationary the lagoon tended to become filled up.

Darwin, instead of meeting each difficulty by a separate assumption, proposed a theory which, by a single assumption, in itself very probable, accounted for all the facts. One of the gravest objections to Darwin's view had been the apparent absence of coral reefs resembling atolls in ancient systems of rocks. That had been removed by the labours of geologists, who were able to point to atoll-like limestones, from 400 to 800 fathoms in thickness, in the Tyrol, the Eastern Alps, and elsewhere. Elevation had recently affected some existing atolls, as might naturally be expected in an unstable area. That fringing reefs, barrier reefs, and atolls should occur together in a single area proved, when the facts were examined in detail, to furnish a striking confirmation of the theory, since these different kinds of reefs were not confusedly intermingled, but arranged along lines which showed a progressive change from elevation at one end to subsidence at the other. The arrangement of atolls in linear series, curving in the Pacific, and straight in the Indian Ocean, was in accordance with the outlines of the surrounding continents, and pointed to deep-seated structure in the earth's crust. Most remarkable in connection with this was the fact that individual atolls were elongated in the same direction as the group of which they formed a part. This was readily explicable on Darwin's theory, but not by the supposition that the elongation was determined by oceanic currents, since these cut the atolls in various directions, not correlated with that of their longest diameter. Further, the areas in which subsidence had occurred were in many cases just those where geologists had reason for supposing that land had existed in secondary times. Particularly was this true of the Indian Ocean, across which, as Neumayer had shown, a great tract of land had probably extended in the Jurassic period.

Dr. Hickson (Section D) said that he agreed with Prof. Sollas in thinking that the Darwinian hypothesis was both clear and beautiful, but that that was about the only point in which he found himself in agreement with the opener of the debate. In his opinion it seemed to be quite possible that some barrier reefs and atolls had been formed during subsidence of the land but in the majority of cases there was very good evidence of recent elevation, and the Darwinian hypothesis would not hold good. Contrary to the statements that are usually made, the outer edge of the reef is seldom, if ever, precipitous, and the evidence tends to show that in most cases the reefs are growing seawards on the talus of their own *débris*. There is a great difference of opinion amongst geologists as to the origin of the Dolomites, and there is no evidence of any fossil coral reef more than a few hundred feet in thickness. In conclusion Dr. Hickson urged upon the combined Sections the importance of initiating some investigations upon the causes regulating the growth and destruction of living coral reefs.

Dr. Rothpletz (Munich) criticised the diagrams and explanation given by Prof. Sollas of the supposed coral reefs of the Dolomites. He did not consider them to be coral reefs.

Mr. Gilbert Bourne confined himself to a few criticisms of Prof. Sollas. It had been stated that reef-building corals flourished best where the breakers are heaviest on the edge of the reef. His own experience was that at these points only a few true corals grow, and that the gardens of coral described by Prof. Sollas were only to be found in quieter spots where the corals were sheltered from the force of the breakers, but bathed by a gentle and uniform current. Photographs of luxuriant coral-beds bore out this assertion. Nor did he agree with the statement that the rocks of which atolls were composed was formed by masses of coral flung over the edge of the reef by the waves. Dr. Guppy had shown that the large masses torn off at the edge of the reef tended rather to roll down the seaward face of the reef, and to form a talus slope. It had been said that soundings of lagoons invariably showed a filling-up and shallowing of the lagoon. On what evidence did this assertion rest? Probably no atoll had been so thoroughly surveyed as the one with which the speaker was personally acquainted, Diego Garcia. He had very carefully compared the soundings made by Captain Moresby in 1837 with those made by H.M.S. *Rambler* in 1885, and found that in every case the soundings were nearly identical, with the exception of a few channels in which, on the whole, the *Rambler* soundings showed greater depths. After referring to Semper's discovery, in the Pelew Islands, of atolls, barrier reefs, fringing reefs, and recent elevated reefs, all found in the same area, the speaker showed that the information just given by Prof. Rothpletz fully corroborated the assertions made over and over again by Murray and Agassiz, that the upward growth of submarine banks was largely due, not to coral growth, but to the accumulation of the calcareous skeletons of mollusca and echinoderms on those banks. Finally, he pointed out that while Prof. Sollas had revived the old theories of a Lemuria and an Atlantis, and had used the existence of the coral islands of the Indian Ocean as evidence of a previously existing continent, he had given no explanation of the fact that the tropical regions of the Atlantic Ocean, across which the old Atlantis was supposed to have stretched, are almost entirely destitute of coral formations.

Prof. Bonney replied to some of Dr. Hickson's criticisms. He cited Masamarhu as a case of a steep slope. He thought judgment on the Dolomites must be reserved. He asked, Was a growing reef ever found deeper than twenty-five fathoms? for that was a point of primary importance.

Sir H. Howorth confined himself to whether coral reefs are now in regions of upheaval or of subsidence. The Pacific islands consist of two regions, the Sandwich Islands, which are an old land surface, and the rest, which have very recently risen from the sea, and so are in an area of elevation, although atolls. This is fatal to Darwin's theory, which depends upon the correlation of reef-building and subsidence.

Mr. Stebbing pointed out that as the young coral animals might settle down on rising or sinking areas indifferently, so reefs might be begun on either, but that only those on an area of subsidence would be under favourable conditions for growth. He also stated that it could not be said that all naturalists who had recently lived on coral reefs were agreed, as Mr. Saville Kent endorsed Darwin's view.

Mr. H. O. Forbes stated that in the Keeling Islands in the Indian Ocean he had found undoubted evidence of elevation, both between two of the islets, and also in the constitution of Horsburgh Island, the largest of the group.

Prof. Sollas briefly replied, and adhered to his original contention.

Section D then took the following, chiefly zoological, papers:—(1) Report on work carried on at the Zoological Station, Naples, viz.—On the action of coloured light on assimilation, by C. C. Duncan, and on the function and correlation of the pallial organs of Opisthobranchiata, by J. D. F. Gilchrist. (2) Report on work carried on at the Biological Station, Plymouth, viz., on Turbellaria, by F. W. Gamble; on decapod larvæ, by E. J. Allen; and how fishes find food, by Gregg Wilson. (3) Report on the production of an index generum et specierum animalium. (4) On seals and whales seen during a voyage to the Antarctic, by W. S. Bruce. (5) On the penguins of the Antarctic, by C. Donald. (6) On the development of the molar teeth of the elephant, with remarks on dental series, by Prof. Cleland, who exhibited a specimen showing the sacular condition.

On Tuesday the remaining papers were taken, viz.:—(1) On cytological differences in homologous organs, by Prof. G. Gilson, dealt chiefly with differences in nephridia. (2) The lateral canal system of fishes, by W. E. Collinge, showing the modification effected by this system in the cranial elements and nervous system, and the evidence the sensory organs afford of the development of the higher sense organs. (3) On the ovipositor of the cockroach, by Prof. Denny. This shows that the ovipositor represents the eighth and ninth sterna, while the two pairs of gonapophyses are developed in connection with these sterna. (4) On a new butterfly, by Mrs. White. (5) On certain gregarinidæ, and the possible connection of allied forms with tissue changes in man, by Dr. C. H. Cattle and Dr. J. Millar. In this important paper the authors described the changes caused in the rabbit's liver by *Coccidium oviforme*, and compared them with the changes produced in glandular organs by cancer. The authors gave reasons for believing the bodies found in cancer to be parasites allied to *Coccidium*. (6) The wings of *Archæopteryx* and of other birds, by Dr. C. H. Hurst. The author regards the two large digits of a bird's wing as IV. and V. (7) The starch of the chlorophyll granule, and the chemical processes involved in its dissolution and translocation, by Horace T. Brown, F.R.S. The author gave an account of the work done by himself and Dr. Morris on the formation of starch and its dissipation. He showed that cane sugar was the first carbohydrate recognisable in the leaf, and that the starch, both in green and colourless parts of the plant, is formed from pre-existing carbohydrates. (8) On nuclear structures in the hymenomycetes, by H. Wazer. The author finds, in contradiction to Rozen's results, that during karyokinesis in hymenomycetes an achromatic spindle exists, and the process is nearly similar to what obtains in higher plants.

CONFERENCE OF DELEGATES OF CORRESPONDING SOCIETIES.

First Conference, September 14.

The Corresponding Societies' Committee was represented by Dr. Garson (in the chair), Mr. Topley, Mr. Symons, and Mr. T. V. Holmes (secretary).

Dr. Garson, the chairman, gave a hearty welcome to the delegates present. These conferences were begun at Aberdeen, in 1885. At that time only twenty-four delegates were appointed, while last year there were forty-two. The number of Corresponding Societies had also increased. This was evidence that the attempt to bring to a focus, as it were, the efforts of the various Corresponding Societies had met with considerable success. But there was also evidence that the societies did not always sufficiently value their privileges. When circulars were sent from the office of the British Association, the majority of the secretaries of the Corresponding Societies did not fill up and return them until they were written to a second time. Again, out of more than sixty societies, only forty-two thought it worth while to send delegates, though it could hardly be a difficult matter to find members able and willing to serve. It was a very great advantage to the workers in the various local societies to have the titles of their papers printed and published in the Annual Reports of the British Association. Then, the Transactions of the various Corresponding Societies were bound and kept for reference in the library of the British Association at Burlington House, while papers read before other local societies were likely to remain unknown or unconsulted. It was most desirable that the British Association should be brought into closer communication with the societies. It had been usual hitherto for representatives from the different Sections to attend the conferences and to mention anything that had been done, such as the appointment of a committee for some special purpose, in which the co-operation of the Corresponding Societies would be advantageous. It would be a good thing that there should be better means of communication between the Corresponding Societies and the secretaries of the various committees appointed by the British Association. A good example of a committee especially needing the assistance of the Corresponding Societies was that appointed by Section H to make an ethnographical survey of the United Kingdom. The first report of this committee had just been presented to the delegates, and Mr. Brabrook, the secretary, would shortly call their attention to it. At their last meeting at Edinburgh some delegates had asked whether the council of the Association might not be able to obtain greater facilities from the railway companies for members travelling to and from these meetings. The council, consequently, appointed a committee, of which Sir Frederick Bramwell was an active member, to see what could be done. The result, however, could not be deemed satisfactory.

The Chairman proposed to take the report, which had been circulated, as read, and would be glad to hear any remarks from delegates regarding the work done during the past year.

Meteorological Photography.—Mr. Symons (Section A) was much indebted to the delegates for the number of photographs of clouds sent in to him up to the present time. He did not press for more, as the committee appointed by the British Association for the Elucidation of Meteorological Phenomena by the application of photography had the very considerable collection of 1467 to deal with. They proposed to select the typical ones, reduce them to a uniform scale, and print perhaps 100 copies of them. They were hoping to publish the atlas during the year, and would then be glad if the meteorologists would take copies. They would be pleased to have additional photographs of lightning.

Mr. A. S. Reid said that the Geological Photograph Committee of the British Association were publishing their fourth report that year. During the year they had received more than 40 new photographs, making the total collection 846. They were all British. Their appeal to the Corresponding Societies had been more successful than in any previous year, but there was still much to be done, and he hoped the delegates would stir up their societies on this point. As to the best camera, the smallest was to be preferred. He had also to report that many prints had been sent in without the names of the societies sending them, that of the photographer, or that of the place photographed. They had decided not to lend any more photographs to the societies, and they would recommend the societies to send duplicate copies. Mr. Jeffs, the secretary of the Geological Photographs Committee, had unfortunately been ill during nearly the whole of the year, and this had seriously hampered their work.

Mr. P. F. Kendall remarked that not one of the Corresponding Societies had given any information to the British Association Committee appointed to record the character and position of Erratic Blocks, though appeals for help had been made. There were whole counties strewn with blocks of which not a single report had been sent.

Mr. Topley inquired whether any society had made researches like those brought before the Conference last year by Mr. Watts in the neighbourhood of Rochdale, as to the quantity of material brought down streams in flood.

Mr. Watts' work had been confined to the Rochdale district, and it was desirable that the results in other districts should be noted. Any local society wishing to do similar work should consult Mr. Watts.

Mr. Slater (Section D) said that it was an interesting fact that a member of the Yorkshire Naturalists' Union recently found the wild maidenhair fern on the northern portion of Morecambe Bay. It would not be desirable that the exact spot should be given. He would also remark that it was better to obtain seeds from these rare plants than to take the plant itself.

In Section E, Mr. M. H. Mills said that a paper on the subject of ordnance maps had been read before the Federated Institute of Mining Engineers by Sir Archibald Geikie, whose chief conclusion seemed to be that nothing could be done without increased funds.

Mr. Eli Sowerbutts said that their member, Mr. Cooke, went before the Departmental Committee, appointed to consider the state of the Ordnance Survey, in order to give evidence. He had suggested to Mr. Cooke that he should write a report on what had been done by the Departmental Committee, which might be presented at the next year's meeting of delegates. The examination on geography mentioned in the report of the Conference of Delegates at Edinburgh did not take place. They would, however, conduct some examinations next year, and he would be glad if the delegates would make their intentions widely known. It was a curious fact that there was no cheap book in existence giving a fairly good account of Yorkshire. The examinations were open to all public and private schools. There would be one on Canada for secondary schools. The latter had been found to know nothing about geography last year, and he looked for some improvement next time.

Mr. Hembry said that he had learned that in a certain county children attending schools were not taught geography in any way. He would like to know if this was the case anywhere else.

Mr. Andrews replied that geography was not a class subject, and was not compulsory. As regards the ordnance maps, the archæologists of Warwickshire, acting on the advice of Mr. Whitaker, forwarded a list of thirteen ancient works to the Ordnance Survey Office, Southampton, ten of which had since been inserted in the map.

Mr. Hembry thought that geography should certainly be a class subject. In secondary schools they absolutely ignored it; but he had been astonished to find that an immense advance had been made in the teaching of geography in primary schools. In many of the latter, museums of commercial products were now being formed.

In Section G, Prof. Merivale had nothing to report about flameless explosives.

Mr. Brabrook (Section H) made some remarks on the progress made by the committee appointed to make an ethnological survey of the United Kingdom, whose first report was in the hands of the delegates. The committee had, he said, obtained, by communication with the Corresponding Societies, a list of nearly 300 villages, with some account of their leading features and peculiarities, all of which were worthy of special examination by the committee. For this result, which was much beyond their anticipations, the Ethnographical Committee gave its most hearty thanks to the members of the corresponding societies who had helped them so efficiently. The next step taken by the committee had been to draw up a brief code of directions for the guidance of those who had been kind enough to offer assistance. This code would be found at the end of the report.

Second Conference, September 19.

The Corresponding Societies' Committee was represented by Dr. Garson (in the chair), Mr. Galton, Mr. Symons, and Mr. T. V. Holmes (secretary).

The Chairman announced that he had received a letter from the President of the Cardiff Natural History Society, stating that Dr. Vachell was unable to attend as a delegate, and that Prof. Viriamu Jones, Principal of University College, Cardiff, had been appointed in his place. He thought it would be best to take first any discussions upon the committees appointed in the various sections.

Mr. Symons (Section A) said that the work of the Earth Tremors Committee was going on under the care of Mr. Davidson, and he did not think that there were other committees connected with Section A that bore upon the work of the delegates. With regard to the report of the Earth-Tremors Committee, he should like to hold it in suspense for a while, in the hope of co-operation with some of the corresponding societies.

In Section C, Mr. A. S. Reid said he had been asked by the Committee to make some remarks. The Underground Waters Committee would present its final report next year, and would be glad to receive further information up to the date of publication. The Geological Photographs Committee thought that the size of photographs should be left to the donors. As to the best camera, further comments from practical photographers were invited; also remarks as to the best methods of printing. With regard to publication, negotiations respecting the proposed album of representative photographs were then in progress. The Erratic Blocks Committee had presented a report, and they were going to publish as much as they could as soon as possible. The Coast Erosion Committee had not sent in a report, though they had plenty of material in hand. The Committee on Type Specimens in Museums was making arrangements for the registration of those specimens, and information was required as to where those specimens were housed.

In Section D, Mr. T.V. Holmes (secretary) read a letter from Dr. Vachell stating that he had come to Nottingham in order to present the Report of the Birds' Eggs Protection Committee that morning, September 16, and regretted he should be unable to stay till the conference on the 19th.

Mr. Slater thought it was high time something was done to protect the eggs of wild birds. Influence might be brought to bear upon boys. He also deprecated the wanton shooting of gulls.

The Chairman stated that the committee had been re-appointed, and that the delegates would in due time receive a final communication on the question.

Mr. Holmes then read a letter from Mr. W. Cole, hon. sec. Essex Field Club, on the maintenance of local museums. Mr. Cole thought that if an annual sum for the maintenance of local museums could be obtained from the Technical Education grants in each county, there would be no great difficulty in obtaining substantial sums towards buildings and fittings. The fear that a museum might not be permanent often kept back subscriptions. Donations, both of money and of specimens, would rapidly come in when once the public felt that the museum would be permanent. And in no way could a portion of the Technical Education grant be better expended than in placing on a satisfactory footing the local museum of the county.

The Chairman hoped that members of the Corresponding Societies would occasionally read papers on the specimens in their local museums, each writer keeping to a certain department. These papers would be catalogued in the societies' list, and brought before the notice of many workers in the same subject elsewhere. They would also be available for reference at headquarters in London.

In Section H, the Chairman commended the Ethnographical Survey (the first report of which had been placed in their hands at the previous meeting) to the attention of the delegates and the societies they represented, and explained in what ways they could assist the committee. Local physical, intellectual and moral characteristics, folk-lore, manners, customs, dialect, and ancient monuments might all be noted by various observers, and the results sent to the Ethnographical Committee. Ancient human remains should be carefully preserved, together with any pottery and implements found with them. If any difficulty occurred with regard to the best mode of making any exploration, information might always be obtained at the Anthropological Institute, 3, Hanover Square, London. In some cases he had known pottery and implements had been carefully preserved, and bones thrown away or buried; in others skulls had been kept by the explorer, and the large bones thrown away. The Anthropological Institute was always ready to advise or to send some one down to examine the remains found. It was better to leave barrows, &c., as they were, unless people were prepared to examine them thoroughly and systematically.

After some remarks on a proposed excursion of the delegates, a vote of thanks to the chairman closed the proceedings.

THE GEOLOGICAL SOCIETY OF AMERICA.

THE fifth summer meeting of the Geological Society of America was held at Madison, Wisconsin, on August 15 and 16; vice-presidents J. C. Chamberlain and John J. Stevenson presiding, in the absence of the president, Sir J. W. Dawson.

The popular feature of the meeting was an illustrated lecture in the Assembly Chamber of the Capitol, by Prof. H. F. Reid, on "The Gravels of Glacier Bay, Alaska." The stereopticon views gave quite the best exhibit of this interesting glacial region that has yet been presented.

The papers presented included a description of a new species of *Dinichthys*, a new *Cladodus* from the Cleveland shale, and a remarkable fossil jaw from the Cleveland shale, by Prof. E. W. Claypole, who is carrying on the work begun by the late Prof. J. S. Newberry on Devonian fossil fishes. The remains described are those of new and remarkable species, one of them showing a degree of specialisation quite surprising for that low horizon. The author even surmised that some of the remains may be amphibian.

Prof. J. J. Stevenson, in his paper on the origin of the Pennsylvania anthracite, seemed to have actually subverted the accepted dogma, that the metamorphosis into anthracite was caused by disturbances of the strata. He showed that the difference between anthracite and bituminous beds is due to circumstances connected with deposition; the former having been laid down rapidly and in thick beds, and having been long under water; they are also earlier than the bituminous beds.

G. Frederick Wright and A. Frederick Wright, in their respective papers on extra-morainic drift in New Jersey, and on the limits of the glaciated area of New Jersey, admitted the correctness of Prof. Salisbury's first announcement that these were genuine glacial deposits, though occurring beyond the limits of the glaciated area.

Edward H. Williams, Jun., in a paper on South Mountain glaciation, described a similar formation in Pennsylvania, where he found transported Medina sandstone and glacial striation.

The programme also included papers on the study of fossil plants, by J. W. Dawson; the Manganese series of the North-Western States, by C. W. Hall and F. W. Lardeson; on the succession in the Marquette Iron district of Michigan, by C. R. Van Hise; terrestrial subsidence south-east of the American Continent, by J. W. Spencer; evidences of the derivation of the kames, eskers, and moraines of the North American ice-sheet, chiefly from its englacial drift, and the succession of pleistocene formations in the Mississippi and Nielson River basins, by Warren Upham; the cenozoic history of Eastern Virginia and Maryland, by N. H. Darton; the Arkansas coal measures in their relation to the Pacific carboniferous province, by James P. Smith; glaciation of the White Mountains, N. H., by C. H. Hitchcock; dislocation in the strata of the lead and zinc region of Wisconsin, and their relation to the mineral deposits, with some observations upon the origin of the ores, by W. P. Blake; geology of the sand hill region in the Carolinas, by J. H. Holmes; notes of geological exhibits at the World's Fair, by G. N. Williams.

BLEEDING BREAD.

THE phenomenon known in Germany as "Blut im Brode," and to us as bleeding bread, has appeared in this country, to no little dismay of the peaceful inhabitants. The subjects of this visitation are not only bread and biscuit, but also boiled potatoes, rice, and other farinaceous substances, on which red stains appear, which resemble blotches of blood. In former times, before their nature was known, these blood stains created much consternation amongst the superstitious as portents of calamity. The first modern naturalist who described it in scientific terms was Dr. Sette, of Venice, who recorded its appearance in Padua, in 1819, and gave it the name of *Zoögalactina imetropha*. In this instance it is stated that "a peasant of Liguara, near Padua, was terrified by the sight of blood stains scattered over some polenta, which had been made and shut up in a cupboard on the previous evening. Next day similar patches appeared on the bread, meat, and other articles of food in the same cupboard. It was naturally regarded as a miracle and warning from heaven, until the case had been submitted to a Paduan naturalist, who easily recognised the presence of a microscopic plant."[1] Subsequently Ehrenberg saw the same production near Berlin, in 1848, and, as usual with him under like circumstances, referred it to the animal kingdom, under the name of *Monas prodigiosa*; but during the same year it occurred in the experience of Dr. Camille Montagne, who saw it on cooked fowls and cauliflower, at Rouen, and it was regarded as an Algoid, under the name of *Palmella prodigiosa*. The first definite record of its occurrence in Britain appears to have been in 1853, when H. O. Stephens communicated an account of it to the Bristol Microscopical Society, and submitted specimens to the late Rev. M. J. Berkeley, who declared it to be identical with the organisms described by Ehrenberg and Montagne, but which he regarded as a fungus.

The record of its appearance at Bristol is to the following

[1] Trouessart, "Microbes, &c." London, 1889, p. 126.

effect[1]:—"I observed at table the under surface of a half round of boiled salt beef, cooked the day before, to be specked with several bright carmine-coloured spots, as if the dish in which the meat was placed had contained minute portions of red currant jelly. Suspecting what these might turn out to be, I directed the beef to be placed aside. On examination the next day the spots had spread into patches of a vivid carmine-red stratum of two or more inches in length. With a simple lens the plant appears to consist of a gelatinous substratum of a paler red, bearing an upper layer of a vivid red hue, having an uneven or papillated surface. The microscope shows this stratum to consist of generally globose cells, immersed in, or connected by, mucilaginous or gelatinous matter. The cells vary in size, and contain red endochrome; they seem to consist of a single cell-membrane, and contain a nucleus. Treated with sulpho-iodine they become blue."

As to its place in the organic kingdom, Mr. Stephens was of opinion that it was a *Palmella* closely allied to *Palmella cruenta*, but distinct, the cells or granules of the latter differing from it, not only in their colour but size, being very much smaller than those of *P. prodigiosa*. As to its propagation, he further remarks that it seems to extend itself by elastically spurting a sort of jet or column of red particles, which Berkeley compared to a jet of blood from an artery, and by this method it was suggested that the extraordinary rapidity with which a large surface becomes covered can be explained. The vitality of the cells is not impaired (within a certain time) by desiccation, even at a high temperature, and when dry they retain their germinating powers for a considerable period.

The spherical cells are filled with a reddish oil, which gives to them a peach-blossom tint, and when transferred to raw meat they assume a splendid fuchsia-colour, resembling spots of blood. The plant is only developed in the dark, and the nitrogen necessary for its nutriment must be derived from the air, especially when developed upon bread. About 1886 an epidemic appearance on the Continent was attributed to this source. Pieces of cooked meat presented a singular carmine-red colouration, and stained vividly the fingers or linen with which they came in contact. These phenomena prevailed regularly for a period of three months. Food cooked over-night was found the next morning covered with red patches, and it then underwent rapid alteration. Coincident with a sudden and considerable fall in the temperature the epidemic ceased, and did not reappear.[2]

Fresenius records the result of his examination of this organism, in his "Beitrage," to the effect that "he took four boiled potatoes, and placed them in a drawer, having previously rubbed two of them slightly here and there with the red substance. After about twenty-four hours, the two potatoes which had not been rubbed, and which had not been in immediate contact with the other two, were affected with fresh spots of the red substance, whilst the spots upon the two which had been rubbed had increased in extent. The spots showed themselves in the form of irregular groups of blood-red drops of different size, which in some places were distinct, and in others had run into one another. The individual bodies of which the spots consist are mere molecules, their diameter varying from one two-thousandth to one four-thousandth of a line. They are mostly round, occasionally oval, and sometimes slightly constructed in the middle, by way of preparation for increase by division into two small round cells. By far the greater number of them, when brought under the microscope in a drop of water, remain at rest—they lie close together in large numbers; when they are more dispersed in the fluid they have a motion which is not distinguishable from ordinary molecular motion. When the drop of water moves they are carried mechanically over the stage like other molecules, and when this motion ceases they remain at one spot in a sort of quivering state until a fresh current carries them in another direction. If the eye be kept carefully upon a part of the stage where the small bodies are thinly dispersed, it will be observed that they passively follow the current of the water, nor, when the current has become sluggish, or has even altogether ceased, are individual bodies ever seen to detach themselves from the group, and take a contrary direction, which real monads would do with great activity."

The present determination of this organism, according to some, is *Micrococcus prodigiosus*, but according to others it is *Bacillus prodigiosus*, and consequently one of the *Schizomycetes*. It has been pointed out that as the temperature rises this *Bacillus* loses its power of forming a pigment, and if it is grown on potato or bread-paste, in an incubator at blood heat, instead of at the temperature of the room, the colour is gradually lost, and the culture no longer smells of herring brine, but the power of forming lactic acid from milk-sugar, with the accompanying precipitation of the casein, is frequently considerably increased; so that it would appear that the energy required for the building-up of the pigment substance was, in this case, diverted into another channel, and lactic acid, and perhaps other substances, are produced in place of the usual pigment.[1]

The reappearance of this organism in this country, during the late hot weather, and especially on cooked potatoes, gives interest to its history, and is sufficient apology for these observations.

M. C. COOKE.

FORTHCOMING SCIENTIFIC BOOKS.

THE autumn publishing season has opened with announcements of forthcoming books to suit all requirements. From this year's list we see that many works of high scientific importance are in the press, but the chief feature is the large number of text-books announced. The work of the Technical Instruction Committees of our County Councils has naturally resulted in the preparation of books on various arts and handicrafts, and since the authors of these books are usually well versed in the technicalities of their subjects, it may be presumed that the 'prentice hand will derive benefit from their literary efforts.

The following books are announced by Messrs. MACMILLAN AND CO:—The Collected Works of Thomas Henry Huxley, F.R.S., in monthly volumes, from October 1. Vol. i. "Methods and Results" (just published); vol. ii. "Darwiniana"; Vol. iii. "Science and Education"; vol. iv. "Science and Hebrew Tradition"; vol. v. "Science and Christian Tradition"; Vol. vi. "Hume." "Systematic Survey of the Organic Matters," by Drs. G. Schultz and P. Julius, translated and edited, with extensive additions, by Arthur G. Green, Examiner in Coal Tar Products to the City and Guilds of London Institute. "Text-Book of the Diseases of Trees," by Prof. R. Hartig, translated by Dr. R. Somerville, Lecturer on Agriculture at Durham College of Science, with a preface by Prof. H. Marshall Ward, F.R.S., with numerous illustrations. "Methods of Histological Research," for the use of students and physicians, by Dr. C. V. Kahlden, Lecturer in the University of Freiburg, translated by H. Morley Fletcher. "Materials for the Study of Variation in Animals." Part i. "Discontinuous Variation," by William Bateson, Balfour Student and Fellow of St. John's College, Cambridge, illustrated. "Handbook of British Marine Fauna," vol. i. Tunicata, Polyzoa, and Echinodermata, by Prof. W. A. Herdman, F.R.S., with numerous illustrations. "The Romance of the Insect World," by Miss L. N. Badenoch, with illustrations. "A Text-Book of Pathology," systematic and practical, by Prof. D. J. Hamilton, vol. ii. "Handbook of Public Health and Demography," by Edward F. Willoughby, Diploma in State Medicine of the London University, and in Public Health of Cambridge University. "The Practitioner," an index to vols. 1–50 of the *Practitioner*, a journal of therapeutics and public health. The three following volumes have been designed to suit the requirements of the examinations of the Department of Science and Art:—"Organic Chemistry for Beginners," by Dr. G. S. Turpin; "Physiography for Beginners," by J. E. Marr, F.R.S., and Alfred Harker, M.A.; "Physiology for Beginners," by Prof. Michael Foster, F.R.S., and Dr. L. E. Shore. "Geometrical Conic Sections," by Charles Smith. "Geometrical Conic Sections," by Asutosh Mukhopadhyay, Fellow of the University of Calcutta. "Geometrical Conics," Part ii., the Central Conic, by John J. Milne and R. F. Davies. "Elementary Trigonometry," by H. S. Hall, Master of the Army Class, Clifton College, and S. R. Knight. "Sketches in Sport and Natural History," by the late Dr. George Kingsley; "The Beauties of Nature," by the Right Hon. Sir John Lubbock, Bart., F.R.S., new edition without illustrations; "The Theory of Heat," by Thomas Preston, with illustrations; "Researches on the Propagation of Electrical Force," by Prof. Heinrich Hertz, of Bonn, authorised translation by Prof. D. E. Jones, with preface by Lord Kelvin, P.R.S., illustrated; "A Text-book on Electro-Magnetism and the Construction of Dynamos," by Dugald C. Jackson, Professor of Electrical Engineering, University of Wisconsin; "The Mechanics of Hoisting Machinery, including Accumulators, Excavators, and Pile Drivers," by Dr. Julius Weisbach and Prof. Gustav Hermann, with 177 illustrations, authorised translation from the second German edition, by Karl P. Dahlstrom, Instructor in Mechanical Engineering at the Lehigh University; "Hydrostatics," by A. G. Greenhill, F.R.S., Professor of Mathematics to the Senior Class of Artillery Officers, Woolwich; "Essays in Historical Chemistry," by Prof. T. E. Thorpe, F.R.S.; "The Rise and Development of Organic Chemistry," by the late C. Schorlemmer, F.R.S., translated and edited by Prof. Smithells, Yorkshire College, Leeds; "Popular Lectures and Addresses," Vol. ii., contributions to Geology, by Lord Kelvin, P.R.S.; "The Life of Sir A. C. Ramsay," by Sir Archibald Geikie, F.R.S.; "A Text-book of the Physiological Chemistry of the Animal Body, including an Account of the Chemical Changes occurring in Disease," by Dr. Arthur Gamgee, F.R.S., Brackenbury Professor of Physiology in the Owens College, with illustrations, Vol. ii.; "Boot and Shoe Manufacture," by C. W. B. Burdett, Head Master City and Guilds of London Leather Trade Schools, with numerous illustrations; "Lead Work," by W. R. Lethaby, with illustrations; "Gold-Milling," with illustrations, by H. Louis; "Elementary Course of Practical Science," by Hugh Gordon.

The CAMBRIDGE UNIVERSITY PRESS announce:—"The Scientific Papers of John Couch Adams," Vol. i., edited by Dr. William Grylls Adams, F.R.S., &c., Professor of Natural Philosophy in King's College, London, late Fellow of St. John's College, Cambridge, with a memoir by Dr. J. W. L. Glaisher, F.R.S., &c., Fellow of Trinity College, Cambridge; "A Treatise on Spherical Astronomy," by Sir Robert S. Ball, F.R.S., Lowndean Professor of Astronomy and Geometry; "A Treatise on the Theory of Functions of a Complex Variable," by Dr. A. R. Forsyth, F.R.S., Fellow of Trinity College, Cambridge; "Plane Trigonometry," by S. L. Loney, Part i., up to and including the Solution of Triangles, is published separately; "Solutions of the Examples in a Treatise on the Elements of Statics and Dynamics," by S. L. Loney, late Fellow of Sidney Sussex College, Cambridge: "Elementary Hydrostatics," by John Greaves, Fellow and Lecturer of Christ's College; "The Steam Engine and other Heat Engines," by J. A. Ewing, F.R.S., Professor of Mechanism and Applied Mechanics in the University of Cambridge; "Elementary Palæontology for Geological Students," by Henry Woods; "Practical Physiology of Plants," by F. Darwin and E. H. Acton. Pitt Press Mathematical Series:—"Euclid's Elements of Geometry," Books v. and vi., by H. M. Taylor, Fellow and formerly Tutor of Trinity College, Cambridge; "Solutions to the Exercises in Euclid," Books i.-iv. (Pitt Press Mathematical Series, by H. M. Taylor), by W. W. Taylor. The Cambridge University Press are also about to publish a series of Natural Science Manuals, which will cover a wide field, some of the books being adapted for beginners, whilst others will deal with special topics, and will be useful only to more advanced students. The series will be divided into two sections, a Biological and a Physical. The former will be published under the general editorship of Mr. Arthur E. Shipley, Fellow and Tutor of Christ's College, Cambridge; it will include "A Manual of Invertebrate Palæontology," by Mr. H. Woods, Demonstrator of Palæobotany at Cambridge, which is now ready; "A Text-book on the Practical Physiology of Plants," by Mr. Francis Darwin, of Christ's College, and Mr. E. Hamilton Acton, of St. John's College, which is in the press; "Works on Physical Anthropology," by Prof. Alexander Macalister; "On the Vertebrate Skeleton," by Mr. S. H. Reynolds, of Trinity College; "On Fossil Plants," by Mr. A. C. Seward, Lecturer in Botany in the University, and "An Introduction to the Study of Botany," by Mr. Francis Darwin, which are in preparation. Other volumes will shortly be announced. The volumes of the Physical Series already arranged for include three by Mr. R. T. Glazebrook, F.R.S., Assistant-Director of the Cavendish Laboratory, on "Light and Heat," "Electricity and Magnetism," and "Mechanics and Hydrostatics"; these will be elementary text-books, based on the Practical Courses of Physics for Medical Students at the Cavendish Laboratory. The volume on "Light and Heat" is in the press, and the other volumes are in preparation.

Messrs. CHARLES GRIFFIN AND CO.'s announcements include:—"A Text-book of Ore and Stone Mining for the Use of Mine-owners, Mine-managers, Prospectors, and all interested in Ore and Stone Mining," by Dr. Clement Le Neve Foster, F.R.S., Professor of Mining, Royal College of Science, H.M. Inspector of Mines; a new Metallurgical series, edited by W. C. Roberts-Austen, C.B., F.R.S., Chemist and Assayer of the Royal Mint, Professor of Metallurgy in the Royal College of Science. (1) "Introduction to the Study of Metallurgy," by the Editor; third edition. (2) "Gold (The Metallurgy of)," by Thos. Kirke Rose; (3) "Copper (The Metallurgy of)," by Thos. Gibb; (4) "Iron and Steel (The Metallurgy of)," by Thos. Turner; (5) "Metallurgical Machinery: the Application of Engineering to Metallurgical Problems," by Henry Charles Jenkins; (6) "Alloys," by the Editor. Technological Manuals: "Oils, Fats, Waxes, and Allied Materials, and the Manufacture therefrom of Candles, Soaps, and other Products," by Dr. C. R. Alder Wright, F.R.S.; "Agricultural Chemistry and Analysis: A Practical Handbook for the Use of Agricultural Students," by Dr. J. M. H. Munro, Professor of Chemistry, Downton College of Agriculture; "Dairy Chemistry: A Practical Handbook for Dairy Managers," by H. Droop Richmond; "Cements: A Practical Handbook on their Manufacture, Properties, Testing," &c., by Gilbert R. Redgrave; "Petroleum: A Treatise on the Geographical Distribution, Geological Occurrence, Chemistry, Production, and Refining of Petroleum; its Testing, Transport, and Storage; and the Legislative Enactments relating thereto; together with a Description of the Shale Oil Industry," by Boverton Redwood, assisted by Geo. T. Holloway. With maps and illustrations. The special features of Mr. Redwood's work will be (1) the hitherto unpublished descriptions of undeveloped sources of petroleum in various parts of the world; and (2) that the testing, transport, and storage from the point of view of legislation, and the precautions which experience in this and other countries has shown to be necessary in the interests of public safety. "A Text-book of Physics: including Properties of Matter, Heat, Sound and Light, Magnetism and Electricity," by Dr. J. H. Poynting, F.R.S., late Fell. of Trinity Coll., Cambridge; Prof. of Physics in the Mason Coll., Birmingham, and J. J. Thomson, F.R.S., Fell. of Trinity Coll., Cambridge; Prof. of Exper. Physics in the Univer. of Camb.; "The Mean Density of the Earth: An Essay to which the Adams Prize was adjudged in 1893 in the University of Cambridge," by Dr. J. H. Poynting, F.R.S., in large 8vo, with bibliography, illustrations in the text, and lithographed plates; "Marine Engineering Rules and Tables (A Pocket-book of): for the use of Marine Engineers, Naval Architects, Designers, Draughtsmen, Superintendents, and all engaged in the design and construction of Marine Machinery, Naval and Mercantile," by A. E. Seaton and H. M. Rounthwaite, with illustrations; "Gas, Oil, and Air Engines: A Practical Text-book on Internal Combustion Motors without Boiler," by Bryan Donkin, with illustrations; "Sewage Disposal Works," by W. Santo Crimp. Second edition, with additional plates; "Engineering Drawing and Design: A Practical Manual for Engineering Students," by Sidney H. Wells, Principal, Battersea Polytechnic Institute, late of Dulwich College. Part I.—Geometry: Practical, Plane, and Solid. Part II.—Machine and Engine Drawing and Design. Complete in one vol., with numerous illustrations and folding-plate; "Applied Mechanics (An Advanced Text-book of)," by Prof. Jamieson, Glasgow and West of Scotland Technical College, with very numerous illustrations.

Messrs. SWAN, SONNENSCHEIN AND CO.'s forthcoming works are chiefly text-books. We note:—"A Student's Text-book on Botany," by Dr. Sidney H. Vines, Professor of Botany in the University of Oxford, editor of "Prantl's Botany," copiously illustrated; "Text-book of Embryology, Invertebrates," by Drs. Korschelt and Heider, of the University of Berlin, translated and edited by Dr. E. L. Mark, Professor of Anatomy in Harvard University, and Dr. W. M. Woodworth, Instructor in Microscopical Anatomy in Harvard University, Part I., illustrated; "The Cell, its Anatomy and Physiology," by Dr. Oscar Hertwig, of the University of Berlin, translated and edited by Dr. H. J. Campbell, illustrated; "Text-book of Palæontology for Zoological Students," by Theodore T. Groom, illustrated; "Lectures on Human and Animal Psychology," by Wilhelm Wundt, Professor of Philosophy in the University of Leipzig, translated and edited by James Edward Creighton, Instructor in Philosophy to the Cornell University, Ithaca, New York, and Edward Bradford Titchener, of the Cornell University; "Handbook of Systematic Botany," by Dr. E. Warming, Professor of Botany in the University of Stockholm, translated and edited by M. C. Potter, M.A., Lecturer on Biology and Botany in the Durham College of Science, illustrated; "Town Flowers," by J. W. N., with a preface by Canon Benham and Prebendary Webb-Peploe; "Zoology," by B. Lindsay, illustrated; "Fishes," by the Rev. H. A. Macpherson; "Flowering Plants," by James Britten, editor of the *Journal of Botany*; "Grasses," by W. Hutchinson; "Mammalia," by the Rev. H. A. Macpherson; "The Natural History and Antiquities of Selborne," by Gilbert White, Bennett's edition, with notes by J. E. Harting, illustrations by Bewick, Harvey, &c., new edition.

Messrs. CROSBY LOCKWOOD AND SONS have in preparation and in the press.—"Machinery for Metalliferous Mines: a Practical Treatise for Mining Engineers, Metallurgists, and Managers of Mines," by E. Henry Davies (illustrated); "The Practical Engineer's Year-book for 1894, comprising Modern Engineering Formulæ, Rules, Tables, and Memoranda, in Civil, Mechanical, Electrical, Marine, and Mine Engineering," by H. R. Kempe; "Practical Building Construction: a Handbook for Students Preparing for the Examinations of the Science and Art Department, the Royal Institute of British Architects, the Surveyors' Institution, &c., designed also as a Book of Reference for Persons engaged in Building" (1000 illustrations), by John Parnell Allen; "Concrete: Its Nature and Uses: a Book for Architects, Builders, and Clerks of Works" (with numerous illustrations), by George L. Sutcliffe; "Tramways: Their Construction and Working, embracing a Comprehensive History of the System; with an exhaustive Analysis of the various Modes of Traction, a description of Rolling Stock, and details of Cost and Working Expenses" (with plates and other illustrations), by D. K. Clark. new edition, in one volume, rewritten and revised; New Volumes of Hasluck's Series of "Handybooks for Handicrafts," viz.: "The Woodworker's Handybook: a Practical Manual on the Tools, Materials, Appliances and Processes employed in Woodworking" (with 100 illustrations); "The Metalworker's Handybook: a Practical Manual for use in Technical Classes and Workshops" (with 100 illustrations); "Wall Paper Decoration" (with numerous illustrations), by A. S. Jennings; "An Astronomical Glossary; or Dictionary of Terms used in Astronomy, with Tables of Data and Lists of Remarkable and Interesting Celestial Objects," by J. Ellard Gore.

Messrs. CASSELL AND CO. promise the following books:—"The Story of the Sun," by Sir Robert S. Ball, F.R.S., Lowndean Professor of Astronomy in the University of Cambridge, about 380 pages, with 8 coloured plates and other illustrations; "The Story of our Planet," by T. G. Bonney, F.R.S., Professor of Geology in University College, London, Fellow of St. John's College, Cambridge, with 6 coloured plates and maps and about 100 illustrations; "The Dawn of Astronomy, a Study of the Astronomy and Temple Worship of the Ancient Egyptians," by J. Norman Lockyer, F.R.S.; "Our Railways, their Development, Enterprise, Incident, and Romance," by John Pendleton, illustrated; "Electricity in the Service of Man, a Popular and Practical Treatise on the Applications of Electricity in Modern Life," with nearly 850 illustrations, new edition, revised by Dr. R. Mullineux Walmsley; "Cassell's New Technical Educator," an entirely new Cyclopædia of Technical Education," with coloured plates and engravings, Vol. ii.; "The Book of the Horse," by S. Sidney, thoroughly revised and brought up to date by James Sinclair and W. C. A. Blew, with 17 full-page collotype plates of celebrated horses of the day, specially produced for this edition, and numerous other illustrations.

The following are included in Messrs. GEORGE PHILIP AND SON's list of forthcoming publications:—"The Mineral Resources of Western Australia, with full descriptions of the Goldfields," by Alfred F. Calvert; "Philips' Anatomical Model," a Pictorial Representation of the Human Frame and its Organs by means of superimposed Plates printed in colours, with descriptive text by Dr. Schmidt, English edition by William S. Furneaux; "Philips' Geological Map of the Environs of London, extending about twenty miles round Charing Cross, showing the Nature of the Soil and the Elevation of the Land," by George Philip (scale, one inch to a mile); "Lessons on Woodwork for Evening Classes, comprising Exercises in the Principles of Joinery, and Studies and Designs for Wood-Carving," with numerous illustrations and explanatory letter-press; published under the direction of the Technical Education of the Hants County Council.

In addition to a number of books of travel, Messrs. SAMPSON LOW, MARSTON AND CO.'s publications will be:—"A History of Scandinavian Fishes," described by B. Fries, C. Y. Ekström, and C. Sundevall, with coloured plates painted from living specimens, and engraved on stone by Wilhelm von Wright, besides numerous text illustrations, second edition, thoroughly revised and completed by Prof. F. A. Smitt; "A School Course in Heat," revised and enlarged, by W. Larden, Assistant Master in the R.N.E. College, Devonport, late Science Scholar, Merton College, Oxford, numerous illustrations, fifth edition; "Chemistry for Beginners," adapted for Elementary Stage of the Science and Art Department's Examinations in Organic Chemistry, by R. L. Taylor, fifth edition, thoroughly revised and partly rewritten.

Messrs. CHAPMAN AND HALL have in hand:—"About Orchids: a Chat," by Frederick Boyle, with numerous illustrations; a book by Mr. Charles Dixon, entitled "Jottings about Birds"; "Woodworking Positions," by W. Nelson, with twelve illustrations by Herbert Cole; "A Text-book of Mechanical Engineering," by Wilfrid J. Lineham, Head of the Engineering Department at the Goldsmiths' Company's Institute, New Cross, late Professor of Engineering at the School of Science and Art and Technical College, Newcastle-on-Tyne; "Illustrations of the Principal Natural Orders of the Vegetable Kingdom," prepared for the Science and Art Department, by Dr. D. Oliver, F.R.S., with 109 plates by W. H. Fitch; "Food, some Account of its Sources, Constituents, and Uses," by A. H. Church, F.R.S., Professor of Chemistry in the Royal Academy of Arts in London, new edition, revised.

The following works will be published by Mr. YOUNG J. PENTLAND:—"Atlas of Diseases of the Skin, in a Series of Coloured Illustrations from Original Drawings, with Descriptive Letterpress," by Dr. H. Radcliffe Crocker; "Manual of Practical Anatomy," by Dr. D. J. Cunningham, Professor of Anatomy and Surgery, Trinity College, Dublin; "Hygiene and Diseases of Warm Climates, in a Series of Articles by Eminent Authorities," edited by Dr. Andrew Davidson, author of "Geographical Pathology," illustrated; "Beri-Beri, Researches concerning its Nature and Cause, and the Means of its Arrest," by C. A. Pekelharing, Professor in the Faculty of Medicine, University of Utrecht, and C. Winkler, Lecturer in the University of Utrecht, translated by James Cantlie; "Atlas of Ophthalmoscopy, a Series of Coloured Plates from Original Drawings, with Text," by W. Adams Frost.

Mr. W. B. CLIVE (University Correspondence Press) will publish:—"Elementary Qualitative Analysis," by William Briggs and Dr. R. W. Stewart; "An Elementary Text-book of Geometrical Conics," by G. H. Bryan; "Geometrical Deductions," by T. W. Edmondson; "Geometry of the Simpler Figures and the Plane, Euclid VI. and XI.," by C. W. C. Barlow; "An Elementary Text-book of Hydrostatics," by William Briggs and G. H. Bryan; "Examples in Magnetism and Electricity," by C. H. Dibb; "An Elementary Text-book of Mechanics," by William Briggs and G. H. Bryan; "The Elements of Trigonometry," by William Briggs and G. H. Bryan; "Co-ordinate Geometry, Part II.," by G. H. Bryan.

In Mr. MURRAY'S list of forthcoming books we find:—"The Life of Prof. Owen, based on his Correspondence, his Diaries, and those of his Wife," by his grandson, the Rev. Richard Owen, with portraits and illustrations. 2 vols. "A Manual of Naval Architecture, for the Use of Officers of the Navy and Mercantile Marine, Ship-owners, Ship-builders, and Yachtsmen," by W. H. White, C.B., F.R.S., Assistant-Controller and Director of Naval Construction, Royal Navy. Third edition thoroughly revised and in great part rewritten, with 150 illustrations.

The announcements of the CLARENDON PRESS include "Mathematical Papers of the late Henry F. S. Smith," Savilian Professor of Geometry in the University of Oxford, with portrait and memoir, 2 vols.; "A Manual of Crystallography," by M. H. N. Story-Maskelyne, F.R.S.; "Observations on some Points connected with Hospital Construction," by Sir Douglas Galton, K.C.B. F.R.S.; "A Monograph on the Oligochæta," by Frank E. Beddard, F.R.S.; "Adler's Alternating Generations, a Biological Study of Oakgalls and Gallflies," authorised translation, by C. R. Straton.

Messrs. Longmans, Green and Co. have in preparation:—"Agricultural Analysis, a Manual of Quantitative Analysis for Students of Agriculture," by Frank T. Addyman; "The Outdoor World, or the Young Collector's Handbook," by W. Furneaux, with 546 illustrations, including 16 coloured plates; "Eskimo Life," by Fridtjof Nansen, author of "The First Crossing of Greenland," translated by William Archer, with illustrations.

Camille Flammarion's "Popular Astronomy" is being translated by Mr. J. Ellard Gore, and will be published by Messrs. Chatto and Windus. This firm will also publish "The Sagacity and Morality of Plants: a Sketch of the Life and Conduct of the Vegetable Kingdom," with coloured frontispiece and 100 illustrations; "Our Common British Fossils, and Where to Find Them, a Handbook for Students," with 331 illustrations; "The Playtime Naturalist," with 366 illustrations.

The volumes on scientific subjects announced by Messrs. Rivington, Percival and Co. are:—"The School Euclid," by Mr. Daniel Brent; "The Beginner's Text-Books of Science": "Chemistry," and "Heat," by Mr. G. Stallard; "Geology" and "Physical Geography," by Mr. C. L. Barnes; "Electricity and Magnetism" and "Mechanics (Treated Experimentally)," by Mr. L. Cumming; "Light," by Mr. H. P. Highton; "Practical Physics," in three parts, by Prof. W. F. Barrett; "Practical Lessons and Exercises in Heat," by Mr. A. D. Hall.

In the list of books about to be published by Messrs. W. H. Allen and Co. we find:—"The Naturalist's Library," each section rewritten by well-known naturalists, edited by Dr. R. Bowdler Sharpe, in 20 vols.; "Handbook of British Hepaticæ, containing Descriptions and Figures of the Indigenous Species of Marchantia, Jungermannia, Riccia, and Anthoceros," by Dr. M. C. Cooke, author of "A Manual of Structural Botany," &c.; "The Flowering Plants of Western India," by the Rev. Alexander Kyd Nairne.

Messrs. Kegan Paul and Co. announce a new volume of "Modern Science Series": "The Fauna of the Deep Sea," by Sydney J. Hickson, Downing College, Cambridge (with illustrations); also a new volume of the "International Scientific Series: "The Dispersal of Shells: an Inquiry into the Means of Dispersal possessed by Fresh-water and Land Mollusca," by H. Wallis Kew, with a Preface by Dr. Alfred Russel Wallace, F.R.S., &c. (with illustrations).

Messrs. George Bell and Sons propose to issue Vol. iii. of the "British Fungus-Flora, a Classified Text-book of Mycology," by George Massee, author of "The Plant World," with numerous illustrations; "The Elements of Applied Mathematics, including Kinetics, Statics, and Hydrostatics," by C. M. Jessop: "Elementary Analytical Geometry," by the Rev. T. G. Vyvyan.

Messrs. Frederick Warne and Co. announce:—"The Royal Natural History," edited by Richard Lydekker, with preface by P. L. Sclater, illustrated with seventy-two coloured plates, and upwards of sixteen hundred wood engravings, by W. Kuhnert, J. Wolf, T. Specht, Gambier Bolton, P. J. Smit, &c., to be issued in monthly parts, beginning this month.

Messrs. Methuen and Co. will add to their University Extension Series a popular introduction to modern physical astronomy, entitled "The Vault of Heaven," by R. A. Gregory; and "Meteorology; the Elements of Weather and Climate," by Mr. H. N. Dickson.

From Messrs. A. and C. Black will come "Investigations in Microscopic Foams and on Protoplasm," by Prof. O. Bütschli, translated from the German by E. A. Minchin, illustrated; and the remaining two parts of Prof. Newton's "Dictionary of Birds."

The following are among the educational announcements of Messrs. Blackie and Son:—"Text-book of Heat," by Dr. C. H. Draper; "Students' Introductory Handbook of Systematic Botany," by J. W. Oliver; "Elementary Hydrostatics and Pneumatics," by R. Pinkerton.

Messrs. W. and R. Chambers will add to their list:—"Electricity and Magnetism," by Prof. Cargill G. Knott; "Organic Chemistry," by Prof. Perkin; "Elementary Science," by S. R. Todd; "Navigation," by J. Don.

Among Messrs. Williams and Norgate's forthcoming books is "A Pocket Flora of the Edinburgh District," by C. O. Sonntag, of the Edinburgh High School, with an Analytical Key to Orders and Genera.

Messrs. J. Hughes and Co. announce "Honours Physiography," by R. A. Gregory and H. G. Wells, and a second edition of Prof. Walker Overend's "Elements of Physiology."

The Religious Tract Society announce "The Romance of Electricity," by John Munro, with illustrations.

TRILOBITES WITH ANTENNÆ AT LAST!

Mr. W. D. Matthew[1] is to be warmly congratulated on being the first to describe Trilobites with visible antennæ. His detailed and illustrated description of a rich find (some sixty specimens) of *Triarthrus Beckii* with antennæ, made by Mr. Valiant in the Hudson River shales near Rome, N.Y., must naturally cause excitement among biologists all over the world.

The complete absence of all traces of visible antennæ, and, further, the failure of Walcott, after the most patient research by means of sections, to discover any antennal system at all, have resulted in the Trilobites remaining without abiding home in the zoological system. They have been Isopods, Phyllopods, and even Arachnida. And now, at last, Trilobites have been found with very pronounced antennæ! The first question we naturally ask is, what light do these antennæ throw upon the affinities of this mysterious group?

According to the description, these organs are long, many-jointed, typical crustacean antennæ. "They come out close together from just under the centre of the anterior border of the head shield." . . . . "Their point of origin seems to be under the front part of the glabella, as they can be traced a little way under the head shield, where they almost coalesce, then turn upwards and outwards and disappear." . . . . "Just over the spot where they come out, the anterior margin of the head shield is arched slightly upwards, seemingly to give room for them to play to and fro."

From these details we deduce the following:—

(1) All Trilobites had antennæ, which except, as far as we know, in the case of *Triarthrus Beckii* alone remained shut in under the head shield.

(2) These ventrally placed antennæ were inserted, approximately, one on each side of the labrum.

It seems to me that these natural conclusions from the facts go far to establish the relationship between the Trilobites and the Apodidæ originally maintained by Burmeister, and recently elaborated by the present writer ("The Apodidæ," "Nature Series," 1892). But however weighty the arguments (amounting, it seemed to me, to a proof) in favour of this relationship, the inability actually to demonstrate the existence of the antennæ was a felt weakness. That weakness has now been finally removed, and my arguments have been fully confirmed, by the finding that the Trilobites had antennæ in practically the same position as the anterior pair in the Apodidæ.

The Trilobites may therefore take a firm place at the root of the Crustacean system, with the existing Apus as their nearest ally.

The modern Crustacea, with their two pairs of antennæ arranged in a group with the eyes at the most anterior end of the body, have then to be deduced from primitive forms in which the antennæ were placed ventrally at the sides of the labrum, and were shut in under a large head shield. *Triarthrus Beckii* shows us one attempt to bring the antennæ forward. A pair of antennæ (presumably the anterior pair) lengthened considerably, and, without apparently changing their places of insertion, projected from under the head shield through a median groove. In spite of this actual discovery, I still think that the method of attaining the same end proposed by me (*loc. cit.*) was the method finally adopted. I suggested two grooves, one on each side of the median line, along which the antennæ moved bodily to the front. This would allow both pairs to act as anterior feelers, whereas the method adopted by Triarthrus would apparently only allow one pair to do so. Further, the piece between the grooves would account for the rostrum, which we know was very early developed. The antennæ in the early Phyllopod *Ceratiocaris papilio* were not long and filiform as in the Trilobite Triarthrus, but look exactly like a pair of Apus antennæ moved bodily to the front.

Whether the remarkable resemblance of the Isopods to the

[1] "On the Antennæ and other Appendages of *Triarthrus Beckii*." (*American Journal of Science*, August, 1893.)

Trilobites is due to direct descent, or is a case of convergence, cannot here be discussed.

We shall wait with impatience for further details of these important discoveries, inasmuch as there seems great promise that the soft black shale to which we owe the fine preservation of the antennæ has also preserved for us further details of the organisation of these interesting fossils. The fragments of limbs shown in the drawings make us eager for more.

H. M. Bernard.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

An influential and well-attended Conference on Secondary Education was opened on Tuesday in the Examination Schools, Oxford. The subjects considered were the need of various types of secondary education in England, with special reference to (1) the curricula and gradation of first grade schools (classical and modern), second grade schools, and higher grade board schools respectively; (2) the provision of preparatory schools for the upper grade of secondary schools; and (3) the relation between secondary schools and the Universities.

Mr. A. Austen Leigh, Provost of King's College, Cambridge, was admitted Vice-Chancellor on September 30. Dr. Peile, in resigning office, commented on the events of the University year. He called special attention to the straitened finances of the scientific departments, and trusted that help might be obtained from external sources. The departments of Engineering, Geology, Astromony, and Pathology appear to be those most urgently in need of additional resources. The Senate would be asked to appoint a syndicate for conducting Examinations in Agricultural Science, being strongly moved thereto by the County Councils and the Royal Agricultural Society. The Galileo Tercentenary at Padua, the Harvey Centenary in Cambridge, and the appointment of Mr. H. Y. Oldham as University Lecturer in Geography, in the room of Mr. Buchanan, were sympathetically referred to.

Mr. R. A. Sampson, Fellow of St. John's College, and Isaac Newton Student in Astronomy, Cambridge, has been appointed Professor of Mathematics in the Durham College of Science, Newcastle.

A new course of lectures on "The Physiology of the Special Senses, chiefly the phenomena of Vision," will be given this term by Dr. W. H. R. Rivers, of St. John's College, Cambridge, beginning on Monday, October 16. The lectures will be accompanied by practical work in the Psychophysical Laboratory.

The Technical Instruction Committee of the Bolton County Council has issued a syllabus of day and evening classes for the session 1893–4. The youth of Bolton can obtain instruction in many of the arts and most of the sciences at their Technical School, and judging from the well-equipped workshops illustrated in the syllabus, excellent courses of manual training are given.

The Entrance Scholarships in Science at St. Bartholomew's Hospital have recently been awarded. The scholarship of £75 in biology and physiology has been given to E. C. Morland, of Owens College, Manchester; the scholarship of £75 in chemistry and physics has been gained by R. H. Bremridge; the junior open scholarship of £150 in biology, chemistry, and physics has been gained by H. A. Colwell; and the preliminary scientific exhibition has been awarded to J. E. Robinson. The Jeaffreson exhibition in classics and mathematics has been gained by G. V. Bull.

A digest of the University Extension Science Lectures, to be delivered this autumn, shows that the movement is doing good work in many parts of the country. In connection with the Cambridge University Extension Syndicate, nine courses will be delivered on Botanical subjects, seven on Natural History, seven on Hygiene and kindred matters, six on Chemistry, and two on the History of Science, while single courses have been arranged in Agriculture, Electricity, and Geology. The programme of the London Society for the Extension of University Teaching shows six courses on Chemistry, four on Astronomy, three on Geology, and the same number on Hygiene. The Oxford University Extension Delegacy have made arrangements for the delivery of sixteen courses on Chemistry, twelve on Hygiene, nine on Agriculture, four on Astronomy, three on Geography, three on Geology, two on Electricity, two on Physiography, one on Light, and one on the Forces of Nature.

SCIENTIFIC SERIALS.

The *American Meteorological Journal* for August contains an important investigation on the movements of the air at all heights in cyclones and anticyclones, as shown by cloud observations made at Blue Hill Observatory. A record was made of the kind of each cloud visible, its direction of motion and relative velocity, and the observations, classified into five levels, were plotted by means of arrows on maps prepared for the purpose. The increased velocity of the wind near the centre of the cyclone and the decreased velocity near the centre of the anticyclone are distinctly shown. The arrows also show that the inclination of the wind to the centres of the two is not the same on all sides. In the cyclone the winds blow most nearly tangential south-east of the centre, and most nearly inward north or north-east of the centre; while in the anticyclone the winds are most tangential north-west of the centre; and most nearly outward south or south-east of the centre. In the cumulus region the cyclonic and anticyclonic circulation are still visible, but the general westward drift has become much stronger, while above that region that circulation is entirely masked by the drift. The diagrams also show that the currents do not all turn to the right as one ascends into the atmosphere, as is usually stated; when the winds have a northerly component, they show that the currents turn to the left as one ascends. The tables show that the circulation of the air is much more rapid in the higher regions than near the earth's surface, both in cyclones and anticyclones.

Bulletin de l'Académie Royale de Belgique, No. 8.—Determination of the constant of aberration, of the parallax of Polaris, of the velocity of the solar system, and of the constants of diurnal nutation, by means of the latitude observations of Gyldén and Peters at Pulkowa, by F. Folie. A further discussion of the evidence for diurnal nutation claimed as discovered by the author, and other deductions from the Pulkowa latitude observations. Among the latter is the R.A. of the apex of the sun's way, 277°, the positive parallax of 0″·05 for Polaris, and the negative correction for the constant of aberration, 0″·037, which harmonises the velocity of light and the parallax of the sun.—Correct determination of the constant of aberration by observations in the prime vertical, by the same author. This shows that the accepted formula for the reduction of prime vertical observations is faulty, and substitutes a corrected one.—Researches on the mono-carbon derivatives, by Louis Henry. This portion of the researches contains a preliminary account of the ammoniacal derivatives of methyl aldehyde.—On a simple method of measuring retardation in minerals cut in thin plates, by G. Cesaro. A compensating quartz prism is placed between the microscope and the mineral, and moved across the field by means of a screw permitting a displacement of 0·05 mm. The tints utilised for the determination of the amount of retardation experienced by the extraordinary ray are those known as sensitive tints, which easily change from a bluish to a reddish violet.—On the nutrition of the echinoderms, by Marcelin Chapeaux. The author maintains that the amibocytes of the cœlomic cavity of starfishes play an important part in the continuation of the process of digestion originated by the radial glands. Small drops of the oils emulsified by the radial glands traverse the epithelium and enter the body cavity. They are then absorbed by the amibocytes, and their duplication is carried out in the interior of these phagocytes, under the influence of an acid ferment.

Bulletin de la Société des Naturalistes de Moscou, 1892, No. 4.—Contributions to the fauna of the Aral Steppes, by A. Nikolsky. List of mammals and birds collected or noticed in the Steppes, with very short remarks.—*Astragalus Uralensis*, a new species, by D. Litwinow.—On the cold of January, 1893, note by B. Sresnewskij.—To the memory of N. I. Koksharoff and A. W. Gadolin, by W. Vernadsky. An excellent summary of Gadolin's work.

1893, No. 1.—On some ecto- and ento-parasites of the Cyclopides, by Dr. W. Schewiakoff (with a plate). A new species, *Trichophrya cordiformis*, is described, also the ento-parasitic slimes of the cyclopides.—On the anatomy of *Siredon pisciformis*, by W. Zykoff (with a plate).—Notes on a new skull of *Amynodon*, by Marie Pavloff (with a plate). The skull has been received from America, and was found in the miocene of the Black Hills, South Dacota.—Catalogue of Lepidoptera of the Government of Kazan (third paper), by L. Krulikovski, containing the Noctuæ.—On the molecular forces in the chemically simple bodies, on the basis of thermodynamics, being the third part of a remarkable memoir by J. Weinberg.—On the development of the ocean, by Prof. H. Trautschold. An attempt to prove that the ocean, at its first appearance, must have been very poor in chlorides as well as in carbonates and other salts.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 2.—M. Lœwy in the chair.—On the Serpent d'eau of the Rhône at Geneva, by M. H. Faye. This paper contains a description of a peculiar phenomenon seen at a weir near Geneva. It is a species of whirl in a vertical plane produced by a recoil of the water from the top of the barrier to a distance of 1·5 m. The axis of the whirl is horizontal, and parallel to the barrier. A delicate experiment performed by the late M. Colladon proved that this "serpent" exercises in its interior a considerable aspiration or suction. The phenomenon is complicated by the superposition of another whirl round a vertical axis in the neighbourhood of places where the barrier is interrupted, and the water is allowed a free fall. In these places conical tubes are formed whose apices descend to the bottom of the river, and into which air is noisily precipitated. Light objects—wood, paper—thrown into the whirlpool, descend, turning upon themselves with extraordinary speed. The whole phenomenon is very transitory and unstable. M. Faye does not share M. Colladon's view that the phenomenon is analogous to an ascending tornado. It has no analogy to a tornado, although it essentially requires a descending whirl for its production.—Observations of the comet Rordame-Quénisset, made with the great equatorial of the Bordeaux Observatory, by MM. G. Rayet, L. Picart, and F. Courty.—Values of the magnetic elements determined by the polar expedition of the Imperial Russian Geographical Society to the mouth of the Lena, by M. le Général A. de Tillo. The values for the magnetic elements at Sagastyr, as found by Captain Jurgens, are the following:—

Declination	4·7° E.
Dip	83·2°
Horizontal intensity	0·072°

G. Neumayer's map shows the greatest error in the declination, which it gives at 11·0° E.—Influence of the state of the surface of a platinum electrode upon its initial capacity of polarisation, by M. J. Colin. The results of M. Colin's experiments are in agreement with M. Blondlot's proposition that gases, and hydrogen in particular, are the cause of changes in the capacity of a platinum-water surface. If, in conformity with this hypothesis, the presence of hydrogen diminishes the capacity, the capacity of an electrode having served as kathode in the decomposition of water is very small; conversely, that of an electrode which has served as an anode, must be very great, since the oxygen set free must have eliminated the hydrogen with which the platinum might have been charged. Chromic acid, being a powerful oxidiser, must act in the same sense.—The fixation of iodine by starch, by M. G. Rouvier. The weights of starch remaining the same, as well as the other circumstances of the experiment, if the quantity of iodine added is increased, the quantity fixed rises at first. If the iodine is employed in sufficient quantity a compound is obtained whose percentage of iodine is always near 19·6, corresponding to the formula $(C_6H_{10}O_5)_{16}I_5$. A higher percentage was never obtained. If the weights of iodine and starch remain the same, as well as the other circumstances of the experiment, and the volume of the mixture increases, the quantity of iodine fixed diminishes, on condition that no more iodine is employed than is necessary to obtain the percentage 19·6. Otherwise, the volume may increase, and yet this percentage may be obtained.

SYDNEY.

Royal Society of New South Wales, August 2.—Prof. T. P. Anderson Stuart, President, in the chair.—The following papers were read:—Notes on the Bingera diamond field, by Rev. J. Milne Curran.—On the occurrence of a chromite-bearing rock from the Pennant Hills Quarry, near Paramatta, by W. F. Smeeth, J. A. Watt, and Prof. T. W. E. David.—Note on the occurrence of barytes at the Five Dock Sandstone Quarry; and note on the occurrence of calcareous sandstone allied to Fontainebleau sandstone from Rock Lily, near Pittwater, by Prof. T. W. E. David.

Linnean Society of New South Wales, August 30.—Prof. Haswell, Vice-President, in the chair.—The following papers were read:—Notes on Australian Coleoptera, with descriptions of new species, part xiv., by Rev. T. Blackburn.—Note on *Colina Brazieri*, Tryon, by Prof. Ralph Tate.—Descriptions of some new species of *Araneidæ* from New South Wales, No. iii. by W. J. Rainbow.—Notes on aboriginal stone weapons and implements, No. xviii.-xx. by R. Etheridge, Junr.—Three additional types of womerah, or throwing-stick, by R. Etheridge, Jun.

CONTENTS.

THURSDAY, OCTOBER 19, 1893.

BRITISH BUTTERFLIES.

The Lepidoptera of the British Islands; a Descriptive Account of the Families, Genera, and Species Indigenous to Great Britain and Ireland, their Preparatory States, Habits, and Localities. Vol. I. *Rhopalocera.* By Charles G. Barrett, one of the Editors of the *Entomologist's Monthly Magazine.* (London: L. Reeve and Co., 1893.)

NOTWITHSTANDING the number of popular books on British insects which are constantly issuing from the press, it is only occasionally that we have to notice the appearance of a work of higher pretensions than this, even as regards our British butterflies. And yet it is of great importance that we should place on record a full and complete account of our native insects as speedily as possible. Much information that might still have been preserved fifty years ago is now irrecoverably lost, for the drainage of the fens has robbed us of many of the British insects which were absolutely peculiar to our country. But some still remain; and notwithstanding the comparative poverty of the British insect-fauna as compared with that of the Continent, the British Islands possess a much larger number of peculiar forms than is generally imagined, and the French entomologists actually call Britain "le pays des variétés."

The volume before us is the commencement of a comprehensive work on the whole of the British Lepidoptera (about 2000 species in round numbers) and is edited by Mr. C. G. Barrett, who is well known to entomologists as one of our best practical workers. He has had unusual facilities for personal observation in many parts of the country, and has devoted much attention to our native Lepidoptera, and more especially to some of the more difficult groups of the smaller moths; but he has hitherto only contributed to periodical literature.

The work appears in monthly parts, with plain or coloured illustrations. It commenced last year, and the first volume, including the butterflies, and illustrated with forty plates representing all the species regarded as undoubtedly British, in addition to numerous figures of larvæ and varieties, is now complete in ten parts, and has been reprinted on smaller paper, and without plates. It appears to us to be a grave oversight that there is no reference to this in the smaller edition, except in the advertisements at the end of the volume. Prominent attention should certainly have been called to the larger edition, even at the risk of injuring the sale of the smaller one, either in the preface or by a conspicuous advertisement.

In his introduction Mr. Barrett gives a concise account of the general structure and metamorphoses of Lepidoptera, and remarks on classification and synonymy. With respect to classification, everyone will agree with him in the following observations:—

"Classification is, however, largely a matter of opinion. The absolute necessity—in books, lists, and collections—for a linear arrangement precludes the possibility of one which is really natural, since, although the relation of groups to each other is often evident, they ramify, extend, intersect and interlace to such a degree that it is only possible to take group after group in as natural a succession as seems to commend itself to the individual writer, with the knowledge on his part that the arrangement is partly the outcome of his own particular views, and that in all probability those of other authors are equally substantial."

But when he adds, "That which has hitherto been followed for our native species does not appear to be disturbed to a very large extent by an examination of the species found in other parts of the world," it is only so far true on account of the vast bulk of the Order having hitherto prevented any rearrangement of the families (the butterflies excepted) in a sufficiently natural series to be regarded in any other light than as tentative.

Mr. Barrett cuts the Gordian knot of synonymy, as is best in a work of limited scope, by quoting every name under which any species is widely known. No other course was open to him, unless he had worked out the synonymy of every species for himself, a work of great labour, difficulty, and at times uncertainty, or unless he had decided to follow some previous author throughout.

Dealing with British Lepidoptera only, Mr. Barrett appears to have almost confined himself to the use of English authors, from the time of Haworth, including an examination of the principal periodicals. A great deal of hitherto unpublished information is also included in the work, from the observations of the author and his correspondents. But little use appears to have been made of continental authors, except as regards the larvæ of some of the species described.

Turning to the body of the work, we find that under each species the dimensions, essential characters, variation, larvæ, pupæ, habits, &c., are discussed in sufficient detail for most practical purposes. A useful feature of the book is the addition of many of the species which have been reputed, on fairly good authority, to have been taken in Britain, but which are still regarded either as accidental immigrants, or as doubtfully British. Of course these notices are much briefer than those of the well-established British species, about which there is no question. But we do not see what has guided the author in his selection of reputed British species; he has included such an insect as *Thais rumina*, a conspicuous South European butterfly, once found flying in Brighton Market, but which could hardly by any possibility be indigenous in Britain, while he makes no mention of many species recorded by the old authors as having been at least casually taken in England. As he has included such species as *Thais rumina* and *Parnassius Delius*, we think he should have given at least a passing notice of every butterfly recorded as having been taken in Britain (except, perhaps, in cases where there was reason to believe that there had been an actual error of identification, or when a careless and ill-informed author like Turton has marked species as British at random); or else have omitted all the reputed British species, except those which there was some ground for believing might ultimately prove to be indigenous. Among the latter were many moths which were really omitted from, instead of inserted in, the British list "without authority," by the late Henry Doubleday, and which have since been proved to be indigenous, and reinstated. But we are glad to find that Mr. Barrett admits *Lycæna argiades* and *Danais Archippus* among our native butterflies. The latter, though an importation from America, has been so frequently taken in England of late years, that it is hoped it may become permanently naturalised. On the other hand, there are several apparently extinct species, formerly common in England, such as *Chrysophanus dispar*, last taken in 1865, as well as others which appear to be now on the verge of extinction as British species, without any obvious reason, such as *Aperia cratægi* and *Polyommatus acis.* In a few years we fear that entomologists may have seriously to consider the desirability of finally erasing several of our British butterflies from our list as absolutely and undoubtedly extinct. *Per contra*, we may look for occasional additions (though very rarely among the butterflies) among species which are possibly overlooked or confounded with others, like *Lycæna argiades* and *Hesperia lineola*, the two latest novelties. In the case of *Lycæna bætica*, first taken in England in 1859, there is good reason to believe that the species is naturally extending its range in North-Western Europe. Possibly this may also be the case with the moth, *Syntomis phegea*, which is said to have been taken once or twice in England of recent years, and which, though gregarious and generally abundant wherever it is found, is excessively local north of the Alps, though there are several isolated colonies in Germany and the Netherlands.

We could have wished that Mr. Barrett had paid more attention both to the foreign literature relating to British butterflies, and to the older English literature before Haworth; but no man can accomplish everything, and within the limits to which he has confined himself his work must be regarded as by far the best and most complete which has yet appeared. W. F. Kirby.

COOKE ON LOCOMOTIVES.

British Locomotives. By C. J. Bowen Cooke. (London and New York: Whittaker and Co., 1893.)

Locomotive engineers, like their brethren in the medical profession, very often differ widely in their practice; again, they often follow the practice of some older locomotive engineer dead and gone, may be. Who can say that the late Mr. William Stroudley has not left his mark on the locomotive design in this country, and that many British railways do not bear his handiwork in the design of their locomotive stock? To the layman the question why certain railways have engines with domes, and other railways have engines without domes, will always remain unanswered. The same may be said of bogies, injectors, pumps, &c.

In the large locomotive works, where engines are built by contract, these divergencies of practice are brought prominently forward, and one is in danger of coming to the conclusion that anything will do in the way of locomotive design. Nor is it only in the design that there is so much variation, for one finds quite as much in the systems of doing work often rigidly specified to be followed.

Another point also deserves attention. Since the use of steel has come into use as a material for the construction of boiler shells, it is amusing to observe the different ways this material is handled, or rather specified to be handled. Some engineers allow the plates to be sheared to size, and the rivet holes punched full size without hesitation; others again partly follow this practice, but require the sheared edges of plates to be planed to a depth of a quarter of an inch, and punched holes to be machined to a depth of an eighth of an inch on the diameter. Another school declines to have punched rivet holes at any price. The same variation in practice holds good with the question of annealing the plates, and particularly the flanged plates which go to form the boiler.

It is possible to take the principal parts of a locomotive and to demonstrate that what is considered good practice by one locomotive engineer is considered by some other to be decidedly wrong, and for this reason no good can be attained by following this view of the question further. Any book, therefore, treating on locomotive engineering will naturally tend to follow the practice of some particular locomotive engineer as regards design, and particularly the details, the principles of course being the same in all cases.

The volume before us "does not profess to be a scientific work; its purpose being more to give the reader, who may not feel disposed to dive into figures and calculations, some information about locomotives in a condensed and intelligible form." This is to be regretted, because there is no modern work on locomotive design available for reference. But on the other hand, the author has written a most readable book, useful alike to the apprentice and lay reader.

The author, being on the locomotive staff of the London and North-Western Railway, naturally follows the practice in vogue on that line, and a better example of good all-round locomotive engineering will be difficult to find.

The volume may be roughly divided into three parts; viz. the early history of the locomotive, details of construction of recent engines, and descriptions of modern locomotives in use on the principal railways in this country. In all three divisions the author has done ample justice to the subject; although, as we have before pointed out, the book would have been of far more value to an engineer had the author gone deeper into the question of design, and particularly the strengths of parts.

Chapter v. deals with the boiler, the most important and delicate part of a locomotive engine; for given a well-made boiler of ample capacity, then the engine will have every chance of being a success. The author on page 91 mentions Bessemer steel as a material for boiler shells n such a way as to give an impression that it is the common practice to use that material for this purpose, whereas Siemens-Martin open hearth steel is generally used, and Bessemer steel is the exception. Further on, the tensile strength of various materials used for making boiler shells is given. Surely the author should also specify an extension or contraction of area as well?

We read that "rivet holes may be drilled, but in general practice with locomotive boilers they are punched when the plates are cold." Has the author ever seen rivet holes punched in a hot plate? It certainly is the practice to punch the rivet holes at Crewe, but no large contractor dreams of punching at all, nor would most engineers allow it to be done; and as regards cost, it is certainly no more expensive to drill.

Fig. 55 represents the arrangement for staying the crown of the fire-box by direct stays to the casing plate. This is said to be "a good arrangement." There are, however, several objections to it, the more important being that no provision is made for the expansion of copper tube plate on raising steam, the first two rows of stays being usually carried by a sling attached to the boiler shell. The old-fashioned roof-bar is again coming into vogue, owing probably to the fact that the fire-box is not held so rigidly, and therefore the plates are not so liable to crack with the constant expansion and contraction.

The chapter on boiler fittings is good, but the asbestos packed fittings made by Messrs. Dewrance and Co. might have been included with advantage. On the subject of cylinders we find much useful information, the latest types being clearly illustrated. Under the heading of general details, the radial axle-box, Adams' bogie and blast-pipe are described, but the bissel truck is not included. This is to be regretted, because it is very commonly in use abroad, and is more efficient than the radial axle-box. The all-important question of brakes is discussed in Chapter xiii. Everybody will agree with the author that it is a pity there should be two brakes in the field, because where vehicles have to run over lines using different brakes, both systems of brake gear are usually fitted: and so thoroughly has this to be done, that in the case of fish trucks used with passenger trains the cost of the brake gear comes to more than half the total cost of the vehicle.

The many improvements recently made in the design of the fittings and gear of the automatic vacuum brake have rendered it most efficient and easily maintained; a sectional drawing of the combination ejector, as made by Messrs. Gresham and Craven, would have been welcome in this chapter. The Westinghouse brake is well described, and is illustrated with the familiar sectional drawings of that company.

Chapter xiv. is on modern locomotives, and is capitally illustrated. The locomotive types on the L. and N.W.R. are described, and a table is given, being a complete list of the different standard classes with the number of engines of each class. Another table gives the numbers and names of all the passenger engines; following this chapter we find the standard types of other companies' locomotives treated in much the same manner. On p. 252 there is evidently an error. The author mentions "Mr. Stirling's 4 ft. coupled inside cylinder engines with 5 ft. 6 in. driving wheels." What does this mean? Page 266 gives the information that the Chatham and Dover Railway has the automatic vacuum as their standard brake. Surely this line is claimed by the Westinghouse Company. Scotch locomotive practice is well represented by Messrs. Holmes and Drummond's fine engines running on the North British and Caledonian railways respectively. Page 286 contains an error in the statement that Mr. Drummond's engines of a particular type are fitted with the Bryce Douglas valve gear. One engine certainly was so fitted, but after a series of breakdowns the gear was done away with, and the ordinary link motion was adopted.

The compound locomotive is treated in Chapter xvi. Both the Webb and Worsdell types are copiously illustrated and described, but there is nothing absolutely new to be learned from a careful perusal of this chapter. No drawing is given of the Worsdell intercepting valve; but this is a mistake which can be rectified in a future edition.

The volume concludes with chapters on lubrication and packing, combustion and consumption of fuel, engine-drivers and their duties, &c. The question of metallic gland packing is just mentioned, and that is all. There are hundreds of engines now running fitted with the Jerome metallic packing, or that of the United States Company, and descriptions of these would not be out of place in this work.

Taken as a whole, this volume contains much readable and useful matter. The author has certainly succeeded in writing a most interesting book, which is sure to leave many clear notions, on the minds of its readers, concerning the practical side of a subject of vast importance. Most of the illustrations are very clear. The printing is good, and the volume is strongly bound.

N. J. LOCKYER.

WEATHER PROPHESYING.

Sécheresse 1893, *ses Causes*. Par l'Abbé A. Fortin, Curé de Châlette. (Paris: Vic et Amat, 1893.)

WHATEVER effect such a period of drought as that through which some parts of England and the Continent have recently past may have had on the harvest, it is pretty certain to be followed with a heavy crop of literature. Some writers content themselves with a simple record of facts, and a comparison with similar experiences in the past; some try to explain the causes, and others have remedies to suggest which may diminish the ill effects of similar periods in the future.

The work quoted above belongs rather to the two last categories, but unfortunately we cannot congratulate the author on his contribution to either the scientific or the economical side of the question. His explanation of the cause of the drought is easily expressed, though we cannot hope that the suggestions put forward will carry conviction to the readers of this journal. In the opinion of the author, the drought is due to three contributory causes. (1) To the sun-spots, which for the three months in question exhibited themselves, it is stated, on the southern side of the sun. (2) To the fact that during the three months, March, April, and May, "Vénus s'est trouvée en opposition constante et prolongée." (3) The third cause is due to the fact that from the beginning of the year the lunar apogee has coincided with the new moon, and the perigee with the full moon.

M. l'Abbé Fortin has apparently many readers and admirers. If we have understood the text correctly, he publishes an almanack in which the weather predictions are given a year in advance, and to judge from the advertisement, these predictions have met with a ready circulation. Further than this, it is mentioned with pardonable pride, that when the gifted author was in need of a micrometer for the prosecution of his studies of these sun-spots, a generous and a sympathising public subscribed 700 francs with a readiness and devotion that should attest the usefulness of his labours and his popularity. With these advantages on his side we feel the responsibility of venturing to disagree with him, or of questioning his figures and his results. Nor is any hope entertained of convincing him of the inadequacy of his arguments, and some apology is perhaps due for pointing out one or two facts which, if they do not convict the reverend Abbé of misrepresentation, exhibit at least a want of candour, which we should not have expected to meet in one of his sacred calling. We may pass over his first argument resting on sun-spots, because it is not impossible but that these do exercise an influence on our atmosphere not yet explained, though we are certain that the warmest adherent of such a theory will find little additional support from the arguments stated by the Abbé. It may not be possible to do justice by a translation to the words "opposition constante et prolongée," as applied to Venus. By "opposition" is evidently meant superior conjunction, but why constant and prolonged? The superior conjunction of Venus did not take place till the beginning of May, and we regret to say that the words "coincident cette année 1893 avec les mois de Mars et Avril" (p. 46) are unwarranted and misleading. The same remark applies to the words (p. 90), "Vénus ne se rapprochait de sa conjonction qu' en Juillet," and it may further be remarked that since Venus was approximately at the same distance from the earth in the beginning of July as at the beginning of March, June ought to have been included in this "constant and prolonged opposition." Again, with regard to the moon's apse, it is declared (p. 90), "il arrivait encore que l'apogée se faisait juste en pleine lune, et le perigée à la nouvelle lune." A comparison of the dates of new and full moon with those of perigee and apogee shows that the Abbé is not more accurate here than in his remarks on Venus. The average deviation for the three months under notice is two and a half days, and in one case the time of full moon was March 31, 19h, while the apogee did not occur till April 5, 7h., or a difference of time of four and a half days. But the curious and to some extent the most interesting feature of the whole is, that the admirers of the Curé will still continue to regard him as an authority, and, what is more to the purpose, eagerly purchase his almanacks, and would continue to do so even if his errors were more palpable—more numerous they could scarcely be.

The remedy which the gifted author would apply to prevent a recurrence of the ill effects which have made themselves felt this year consists in an extensive system of irrigation. Doubtless financial considerations would enter in a perplexing manner into such a scheme, and prevent it becoming a part of practical agriculture. But the knowledge of local circumstances which the Abbé probably possesses, and certainly we do not, permits him to speak with an authority we do not like to question.

OUR BOOK SHELF.

Geological and Solar Climates: their Causes and Variations. A Thesis. By Marsden Manson. (London: Dulau and Co., 1893.)

Several thinkers have from time to time set to work to enlighten their fellow-creatures on the subject of the cause of the Ice age, a period when ice covered quite generally both the temperate and the tropical areas. Each one has in his own way added something towards the solution of this problem, whether that something was large or small, but the theory that will produce conviction in all minds, or rather in the majority of minds, has yet to come. The causes which have been suggested are many and varied. Some say the age was due to a decrease in the original heating of the globe; changes in the elevation of the land, and therefore varied land and water distributions; changes in the position of the axis of the earth; while others account for the phenomenon by suggesting a period of greater moisture in the atmosphere; variations in the amount of heat radiated by our sun; variations in the absorbing power of the sun's atmosphere; variations in the temperature of space; coincidence of an Aphelion winter with a period of maximum eccentricity of the earth's orbit; a combination of the last mentioned with that of changes in the elevation of the land; and lastly, the explanation recently put forward by Sir Robert Ball.

In the present thesis the author, after reviewing briefly the suggested explanations, goes back to the idea of the decrease in the original heating of the globe, and on that builds up a very plausible theory. To state briefly this theory, one must mention that two sources of heat were at work—first that of the resident or internal heat of the earth, and second that of the sun. As the earth passed from the era in which its climates had been controlled by internal heat to one in which solar heat predominated, uniform climates "must have been passed through during which isotherms were independent of latitude." Before the era was reached at which the sun had complete control over the climates, the author says the continental areas must have been glaciated, independent also of latitude.

To state in so many words the direct *cause* of the Ice age, he says that it is due to the remarkable properties of various forms of water in relation to heat and cold. As vapour it played an enormous part in the loss and receipt of heat by radiation, as water it was the last to retain "the effective remnant of earth heat, on account of its high specific heat, and as ice it was able to store a great amount of cold."

The author then deals in detail with the way these three forms of water played their part in this stupendous phenomenon.

The end of the Ice age was brought about so soon as the solar heat could find its way to the earth's surface; the air being cleared of obscuring clouds and fogs by the chilling of the oceans and the glaciation of continental areas.

The first zone over which the solar energy would first establish its power would be the torrid zone; travelling polewards the glacial conditions would gradually be removed upon lines parallel with the present isotherms.

More on the subject need not be said here, but we would recommend any one who takes an interest in this problem to give this book a perusal, for although there may be many who would not agree with the writer in all points, yet he has made an honest and plausible attempt at suggesting a cause of one of the most difficult and yet most fascinating problems with which we have to deal.

A Manual of Electrical Science. By George J. Burch. (London: Methuen and Co., 1893.)

Of the many useful volumes in the University Extension Series published by Messrs. Methuen, this is one of the best. "I have written," says the author, "not for wealthy amateurs, nor for people who do not care to think, but for men and women who have to give up something else to spend a sovereign on their own education. Nearly all the apparatus described in this book can be made by anyone with a few tools and a little finger-skill." In conformity with this laudable desire, technical terms are rarely introduced without being explained, and by simple words and apt illustration the way to electrical knowledge is made as easy and pleasant as it possibly could be. Indeed, popularity of style appears to be the book's sole *raison d'être*, for, with one or two exceptions, the facts described are to be found in a number of elementary text-books. However, it can be said that there are very few, if any, books of the modest dimensions of the one before us in which so much information is imparted in a more popular manner. The descriptions of experiments and principles are easy reading without being diffuse; the hydrostatic and other analogues are numerous, yet they are never used where likely to lead to a misconception. The illustrations, however, are not worthy of the text. They should have been far more numerous and less sketchy in order to appeal to the public for whom the book has been specially designed.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Supposed Glaciation of Brazil.

IN the second volume of NATURE, p. 510, I reviewed the late Prof. Hartt's "Geology and Physical Geography of Brazil," and called attention to the author's views, as well as those of the late Prof. Agassiz, relating to the supposed glaciation of that country. From their very positive statements I concluded that the evidence as described by them did actually exist, and that until it was disproved it should not be ignored. In my "Darwinism," p. 370, I stated, on the authority of my friend, Mr. J. C. Branner, now Professor of Geology in the Stanford University, California, who succeeded Prof. Hartt in Brazil, and had a much more extensive knowledge of the country, that the supposed glacial drift and erratic blocks were all results of subaërial denudation. Recently, however, Sir Henry Howorth has quoted some passages from my review in illustration of the wild and incredible theories of some geologists, as samples, in fact, of the "Glacial Nightmare"; and, as no authoritative disproof has yet been given of the exceedingly strong and positive statements of Agassiz and Hartt, I beg leave to lay before the readers of NATURE some extracts from a paper on "The Supposed Glaciation of Brazil," by Prof. Branner, which will shortly be published, and of which he has kindly sent me a type-written copy in advance. As a partial justification of what has now proved my too hasty acceptance of the statements of these gentlemen, I will give one passage in which Prof. Agassiz refers to the supposed glacial phenomena near Ceara:—"I may say that in the whole valley of Hasli there are no accumulations of morainic materials more characteristic than those I have found here, not even about the Kirchel; neither are there any remains of the kind more striking about the valleys of Mount Desert in Maine, where the glacial phenomena are so remarkable; nor in the valleys of Loch Fine, Loch Awe, and Loch Long, in Scotland, where the traces of ancient glaciers are so distinct." Both Agassiz and Hartt were equally strong as to similar phenomena near Rio.

It is to be first noted that Hartt had only spent eighteen months in Brazil when he wrote his book, and his views on the glacial phenomena were thus based on a very hasty survey of that enormous territory. Prof. Branner went with him when he again visited Brazil in 1874, helped him in his geological work till his death in 1877, and himself remained five years longer making a geological survey of the country; and he states that, before his death, Hartt's views underwent a radical change. Prof. Branner says:—

"Under his direction I did more or less work in the mountains about Rio de Janeiro for the purpose of sifting the evidence of glaciation in that region, and I am glad to say, in justice to the memory and scientific spirit of my former chief and friend, that long before his death he had entirely abandoned the theory of the glaciation of Brazil, and that the subject had ceased to receive further attention, even as a working hypothesis."

A few extracts must now be given showing to what causes the phenomena which deceived these observers are really due. And first as to what were supposed to be erratic boulders often embedded in boulder clay.

"The boulders believed to be erratics are not erratics in the sense implied, though they are not always in place. The first and most common are boulders of decomposition, either rounded or subangular, left by the decay of granite or gneiss. Sometimes they are embedded in residuary, and therefore unstratified, clays, formed by the decomposition in place of the surrounding rock. And everyone has heard of the great depth to which rocks are decomposed in Brazil. The true origin of these boulders and their accompanying clays is often obscured by the 'creep' of the materials, or in hilly districts by land slides, great or small, that throw the whole mass into a confusion closely resembling that so common in the true glacier boulder clays. In this connection too much stress cannot be placed upon the matter of land slides; they are very common in the hilly portions of Brazil, and aside from profound striations and faceting produce phenomena that, on a small scale, resemble glacial till in a very striking degree." . . . .

"The second method by which these boulders have been formed is quite similar to the first, but instead of being cores of granite or gneiss, they have been derived by the same process of exfoliation and decomposition from the angular blocks into which the dikes of diorite, diabase, or other dark-coloured rocks break up. Their colour marks them as quite different from the surrounding granites, and the dikes themselves are almost invariably concealed. The residuary clays derived from the decomposition of these dikes are somewhat different in colour from those yielded by the granites, so that when 'creep' or land-slides add their confusion to the original relations of the rocks the resemblance to true glacial boulder clays is pretty strong. The chance of discovering the source of such boulders is further decreased by the depth to which the mass of the rock has decayed, and by the inpenetrable jungles that cover the whole country, and so effectually limit the range of one's observations. Dikes, such as these last mentioned, are not uncommon in the mountains about Rio de Janeiro. Indeed, what have generally been regarded as the very best evidences of Brazilian glaciation, some of the boulders near the English hotel at Tijca, fall under this head, though some are of gneiss. The fact is that the great mountain masses about Rio are of granite or gneiss, while some of the boulders come from the dikes of diabase or other dark-coloured rock high on their sides—dikes which were not visited by Agassiz or Hartt."

Prof. Branner then describes a third class of supposed erratic, derived from certain sandstone beds of the tertiary deposits, which, by exposure, change to the hardest kind of quartzite, and when the surrounding strata are removed by denudation, and a few blocks of this quartzite are left, they are so unlike the rocks by which they are surrounded that unless the observer has given a special study to the tertiary sediments, he is liable to be misled by them.

The wide-spread coating of drift-like materials tha covers considerable areas of the country, consisting of boulders, cobbles, and gravels, sometimes assorted and sometimes having clay and sand mixed with them, are then described, and are shown to be due to the denudation of the tertiary beds during the last emergence of the land, aided by subsequent subaërial denudation and surface wash. Prof. Branner thus concludes:—

"I may sum up my own views with the statement that I did not see, during eight years of travel and geological observations that extended from the Amazon valley and the coast through the highlands of Brazil and to the head waters of the Paraguay and the Tapagos, a single phenomenon in the way of boulders, gravels, clays, soils, surfaces, or topography, that required to be referred to glaciation."

The very clear statement above given of the real nature of the phenomena which deceived Prof. Agassiz and Mr. Hartt, is very instructive, and it shows us that a superficial resemblance to drift, boulder-clay, and erratic blocks, in a comparatively unknown country, must not be held to be proofs of glaciation.

We require either striated rock surfaces or boulders, or undoubted *roches moutonnées*, or erratics, which can be proved not to exist sufficiently near to have been brought by "creep" or land-slides. In view of these liabilities to error, we may be almost sure that the supposed evidences of glaciation described by the late Mr. Belt in his "Naturalist in Nicaragua" (p. 260), are explicable in the same manner as the Brazilian evidences, since he nowhere found glacial striæ or any boulders that could be proved to be true erratics; and this is the more certain because he himself states (p. 265), "I have myself seen, near Pernambuco, and in the province of Maranham, in Brazil, a great drift deposit that I believe to be of glacial origin."

All students of the past and present history of the earth are indebted to Prof. Branner for having relieved them of a great difficulty—a true glacial nightmare—that of having to explain the recent occurrence of glaciation on a large scale far within the tropics and on surfaces not much elevated above the sea-level. ALFRED R. WALLACE.

Telegony.

DR. ROMANES' letter inviting a discussion concerning the remarkable phenomenon of telegony will be welcomed by many who have felt that too little notice has been paid by men of science up till now to one of the most obscure problems of heredity. At the conclusion of his remarks, Dr. Romanes rejects Prof. Weismann's hypothesis that sperm elements are capable of penetrating into the ovary, and fertilising immature ova *in situ*, on the ground of their obvious incapability of doing so. It seems, however, possible to doubt whether the spermatozoa are so incapable of penetrating such tissues as the stroma surrounding an ovarian follicle. Although, as far as I am aware, the actual penetrating of spermatozoa through ovarian tissues has in no case ever been shown to take place, yet we are bound to take it for granted that in some cases this actually occurs, from facts observed in many Invertebrata.

Prof. Whitman, in an exhaustive paper published in the *Journal of Morphology*, January 1891, has collected a considerable mass of evidence to show that in many widely-differing animal groups the spermatozoa make their way through the external body wall at many different points, usually a large number being bound together to form spermatophores. Perhaps the best examples of animals where this occurs are found among the Turbellarians and Leeches. In these forms the spermatozoa pass directly through the epidermis, basal membrane, and the layers of muscular and connective tissue till they reach the body cavity. Here the spermatophores break up, and in some instances the individual spermatozoa undoubtedly must penetrate the wall of the ovary in order to fertilise the ova *in situ*.

As in many mammals, the immature ova lie very near the surface of the ovary, it does not seem to be beyond possibility that even in the higher vertebrates some similar process may occur.

On the other hand, as Prof. Weismann points out, if such be the case we should expect to find animals pregnant several times in succession after once being crossed, of which no instance has ever been recorded.

Dr. Romanes' suggestion that the followers of Weismann may explain the facts of telegony by supposing the spermatozoa to disintegrate and that their "ids" and "determinants" somehow enter the unripe ova, must for the same reason be dismissed as impracticable, unless it be assumed that enough "ids" never reach one egg to supply the place of those "ids" which have been got rid of by the reducing division of the egg nucleus, and would be replaced in the ordinary course of things by the spermatozoon. Such an assumption would be obviously unscientific and unwarrantable.

It seems, therefore, unsafe, until more definite experimental work has been done with regard to this obscure and interesting problem, to attempt to give any very definite explanation of the facts as they now stand, if we adopt Prof. Weismann's, views as to the continuity of the germ plasm. The facts, as Dr. Romanes very rightly insists upon, show that telegony is on the whole, of very rare occurrence, and on this account it is premature to go so far with Mr. Spencer as to maintain that the few isolated instances of telegony are sufficient to knock down at a blow the far-reaching theories of heredity which Prof. Weismann has put forth. M. D. H.

September 29.

The Use of Scientific Terms.

PROF. LODGE has made a valuable statement regarding scientific terms in last week's NATURE as follows:—"The words used in the current language of biology are extremely classical and as unlike the language of daily life as can be contrived. This is done to keep free from the misunderstandings arising out of the attempt to give to popular words a scientific, *i.e.* an accurate meaning." Botanists have not always been as careful as Prof. Lodge would have us believe, and as an instance to the contrary I would cite the following: I was recently lecturing on forest utilisation, and used the word bark in its ordinary meaning of the outer envelope of a tree. One of the students in the class interrupted me to point out that I was speaking loosely, as *bark* is now a scientific term, meaning the transformed outer envelope of a plant, the German *Borke*, after the growth in it of corky or stony tissues.

I appealed to the sense of the class as to whether botanists have any right to adopt a common English word for something beyond its ordinary meaning, and the class took my view of the subject unanimously, carrying eventually even the objector with them.

The substance now scientifically termed *bark* might be styled *rhytidome*, as is done in France (*vide* "Flore Forestière," by A. Mathieu, edition 1887, p. 595); or can any reader of NATURE propose a better term? W. R. FISHER.

Coopers Hill, October 16.

Rustless Steel.

SOME months ago I noticed, in *The Field*, the statement that steel containing twenty per cent. of nickel was free from rust and, on that account, very suitable for the manufacture of small arms of high quality. From its use in the manufacture of ordnance and armour-plate I presume, moreover, that the nickel alloy does not compare unfavourably with ordinary steel in point of tenacity and hardness.

If this proves to be the case—and it is the object of this letter to elicit the information from some of the numerous readers of NATURE—nickel-steel would form an invaluable material for the construction of certain parts of astronomical and geodetic instruments, notably the pivots and axes, which, as made at present, slowly deteriorate from rust when of steel, or from wear when of bronze. With geodetic instruments, continually set up as they are in exposed situations, sometimes near the sea, it is seldom there is not, after a few years' use, evidence of rust enough on the pivots to have destroyed much of the extreme perfection of figure attained by makers like Repsold or Ertel. The wear of bronze pivots is even worse. I am informed that the earlier meridian observations at a leading observatory are not comparable in accuracy with those taken after the original bronze pivots had been replaced by steel ones.

Cape Town, September 27. H. G. FOURCADE.

RESEARCH LABORATORIES FOR WOMEN.[1]

THE session which we inaugurate to-day will in the future be regarded as of prime importance in the history both of Bedford College and of the higher education of London at large.

It will be remembered in the history of London, for in the course of it the Gresham Commissioners will issue their long-expected report. Whatever the nature of that report may be it will be important; most important if the Commissioners succeed in solving the difficult problem which has been proposed to them, and enlist in favour of their recommendations so strong a sentiment of public approval that a teaching university is at length established on the lines which they lay down. Important, though no doubt less important, if they add to the long list of failures to find the true solution, and thus only prove that another route to the desired end is barred.

As regards Bedford College itself, we meet this session under the shadow of a loss. Miss Martin, for many years the Lady Resident, who has done so much in helping to

[1] Inaugural address delivered at the Bedford College for Wome , by Prof. A. W. Rücker, F.R.S.]

guide our institution amid the difficulties which have surrounded it, has retired from her post. Many here have already had opportunities of expressing their regrets to her in person, but I feel sure that none interested in Bedford College would wish the first meeting of this session to pass without our conveying to Miss Martin the assurance of the affection with which she has inspired many generations of Bedford College students, or without our telling her once more of our hopes that she may enjoy for many years the rest she has so well earned.

In an inaugural address, however, it is natural to look rather to the future than to the past.

It has been thought well that the organisation of the College should be brought into closer approximation to that which obtains in most similar institutions, whether intended for the education of men or of women. We have now a Lady Principal. It would be impossible in the presence of Miss Penrose to express fully how much we hope from her in the future; it may be sufficient to say that we welcome her as the daughter of a distinguished scholar, and as one who has shown herself capable of climbing the very highest rounds of the ladder of learning. Miss Penrose was selected as Principal by the Council from among a group of candidates, of whom several would have adorned the post, and we believe that the large share in determining the future of Bedford College, which she must now take, has been placed in safe hands.

On the occasion of this new departure it may be well to consider how widely the position of those who are now engaged in working for Bedford College differs from that of its founders.

When the College was first instituted the very principle which it was intended to embody was disputed on all hands. It was denied that the doors of the Temple of Learning should be thrown open to women equally with men; that there is no crypt, however dark, no chapel, however sacred, which may not be entered by both alike.

That principle has now been vindicated. Women are working side by side with men in the same universities, competing with them in the same examinations, and proving by their successes that they can bear a worthy part in the intellectual strife of the schools.

But if in this respect the Council have not to face the prejudices which their predecessors overcame, they have to encounter new difficulties caused in part by the very success of the principle for which their predecessors contended.

Bedford College was the first institution designed for the introduction of women to the higher learning, but unfortunately, or, as the cause is greater than the College, I should perhaps say fortunately, it had no patent rights in the theory which it first illustrated. Rivals, friendly rivals, have sprung up, and in some respects they possess advantages we cannot claim.

Some share the charm of the surroundings and the prestige of the names of the older universities. Another, near London, has wealth to which we have not yet attained. As women's colleges have become more numerous, the beauty of their buildings has increased, the standard of their equipment has improved. To beauty of outward adornment we cannot in York Place pretend, but I would not have dwelt on this point to discourage you. Our laboratories, though small, are well fitted; the art studio, the class and lecture rooms are sufficient for all the claims that are at present made upon them, and we may truly assert that Bedford College, though without the advertisement of external decoration, is adequately equipped for its great task.

Another change which has taken place since Bedford College was founded is in the ideals of those who are engaged in promoting the higher education.

When the College was first inaugurated the great examination craze was at, or was approaching, its height. Since then we have learnt that that method of testing ability is not all-sufficient, and signs are not wanting of a growing disbelief in its efficacy, especially when applied to very advanced students.

The Education Department is laying greater stress on inspection and less on examination. In the University of London the note-books of the work done by scientific students in the laboratory are submitted to the examiners, thus recognising work done outside the examination room.

At Cambridge the Smith's prizes are given for successful theses instead of after an examination test.

To have completed an original research now carries a man further towards his fellowship than all the triumphs of the Schools.

In the University of London the degree of Doctor of Science is given without further examination, if the candidate can prove that he has added to knowledge on the subject he professes.

I am told that there is at present a movement on foot at Oxford for giving to those who have carried out a successful research, what is still to some Englishmen almost inconceivable, an examinationless degree.

It is perhaps chiefly in the mathematical and physical sciences that this movement is most noticeable, and it is largely based upon the growing conviction of both teachers and students, that it is, if not useless, at all events unsatisfactory to master all the intricacies of a mathematical or experimental machinery for investigating nature, if the knowledge gained with much pain and labour is not turned to account.

Every man who has solved a mathematical problem has done work which is, as far as he is concerned, original, and it is absurd to train men so as to endow them with a special facility for such work, and yet to do nothing to show them in what direction their exceptional attainments may be of real service.

A student who has mastered a science but complains that he can add nothing to knowledge, is like an athlete who has learned to run well on a cinder track, but fails on the high road.

More and more stress, then, is now being laid on the power both of teacher and students to use their knowledge. It is no exaggeration to say that original papers are produced in the principal London colleges by the score. If we turn to the provinces we find that the Commissioners of the 1851 Exhibition give scholarships to those among the provincial students whom their colleges recommend as capable of undertaking advanced scientific work. And here it may be noticed that examination has again been dispensed with. In the old days the candidates would have been selected after a centralised examination held in London, whereas now the Commissioners are content—and, in my opinion, very properly content—with the recommendation of responsible authorities.

In view then of this great change in the aims and objects of the higher education, I want to impress upon you that fact that if Bedford College, if women's colleges in general are to hold the high position which the success of their students in the examination room has won for them, they must become places, not merely for acquiring knowledge, but for adding to it. I do not think that it can be honestly said that up to the present time the success of women as investigators has, in spite of some notable exceptions, been as great as their rapid and extraordinary achievements as students would have led us to expect. Nevertheless, if the fundamental idea of our founders is to govern us in the future as it has guided us in the past, the students of Bedford College must distinguish themselves in the research laboratory as they have often distinguished themselves in the struggle for a degree. In undertaking this task, many of them possess one qualification for success which most men lack: they have, at all events, time at their disposal.

Do not let me be misunderstood. I am far from desiring that the students of Bedford College should leave its walls impressed only with the importance of adding to knowledge, and inclined to neglect other and, at least as urgent duties. In my opinion, no man or woman can afford to cultivate any one part of their nature to the exclusion of the others. Sad stories have sometimes been told of homes in which work has been done which will never be forgotten, but done at the cost of all the brightness and happiness which are usually associated with the name of home. This want of the sense of proportion, of the relative importance of different claims, casts a shadow on the brightest intellectual fame. I am not asking for such sacrifices. I believe that in general they are absolutely unnecessary. But where the over-mastering curiosity of the born investigator exists, it will find a career, which may indeed involve self-sacrifice, but which need make no harsh demand on others.

There are, to my knowledge, at the present moment a large class of men who are living more hardly than they otherwise might live, who are cheerfully surrendering days which might be given to pleasure or to money-making, and are spending laborious nights, simply because they are impelled by the desire to add something to the pile of knowledge which our race is through the centuries accumulating. It cannot but be that if the same spirit animated the women and girls of this generation, many would be found among them who, without neglecting any duty, would work with the same energy for the same object.

It is possible that some of my hearers may accuse me of holding up an impossible ideal. My answer is that the founders of Bedford College held up to their generation an ideal which was then regarded as impossible but which has nevertheless been realised. Women, if they please, can now be educated to the same high level as men. I in turn venture to hold up to you an ideal at which Bedford College should aim in the future. It is that it should be known as a place of learning as well as a place of education, as a place where not only is the number of those who know added to, but where knowledge itself is increased.

THE INNER STRUCTURE OF SNOW CRYSTALS.

THE ice and snow crystals photographed and described by me[1] may be referred to the following types.

I. Crystals developed in the direction of the vertical axis. (*a*) Hexagonal prisms. (*b*) Bottle-shaped prisms. (*c*) Needles.

II. Tabular crystals. (*a*) Hexagonal tables. (*b*) Stellated tables. (*c*) Dendritic tables.

III. Crystals equally developed along the vertical and lateral axes.

Among these groups, types I. (*c*) and III. are in no way different from the ordinary hexagonal crystals, and accordingly of less general interest. The former, I. (*c*), is common in drifting snow; to the latter belong the sharp edged hexagonal prisms *without cavities*, which compose the under layers of the snow covering. They are never found among the snowflakes, and are accordingly originated by a molecular change in the snow covering. Type II. (*c*) comprises the relatively large dendritic crystals with complicated ramifications which are visible even to the naked eye as handsome regular stars. They have been figured and described by several observers, from Claus Magnus and Keppler to Scoresby and Glaisher, and I shall therefore not dwell upon them in the present paper. Of the remaining extremely interesting types (I. *a*, *b*; II. *a*, *b*), which, owing to their microscopic dimensions, have hitherto received no attention from men of science, I give a brief description.

I. (*a*) *Hexagonal Prisms.*

Fig. 1 shows the commonest type. It is bounded by the basal planes and the hexagonal prism, and of interest on account of the *hour-glass shaped cavities* invariably present within the crystal. These are, as shown by the figure, widest near the two basal planes, where they are bounded by a negative hexagonal prism; nearer the centre they contract again to expand in the form of two bulbs, elongated to points and confluent. The shape of the cavities is almost always the same. Crystals of this type are very small (about 0·5 mm. long), and the inner structure only distinguishable under the microscope. They are common in drifting snow.

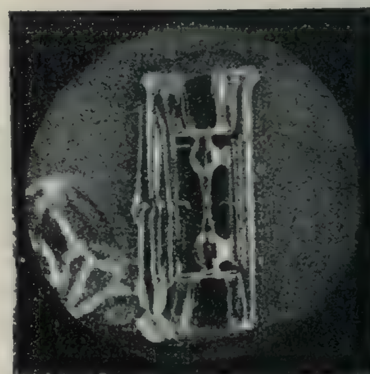

Fig. 1.

I. (*b*) *Bottle-shaped Prisms.*

The bottle-shaped crystals of elongated, prismatic form have the appearance shown in Fig. 2. Like the crystals of the preceding type, they are bounded by an hexagonal prism and the basal plane; but one end is pointed, and the crystals accordingly hemimorphic. The bottle-shaped crystals also contain cavities, less regular, however, than those in the crystals of the preceding type. The following circumstance attaches a special interest to these crystals. On February 8 there was a rather sparse fall of agglomerations of bottle-shaped crystals such as are shown in Fig. 2. *The cavities in these crystals proved under the microscope to*

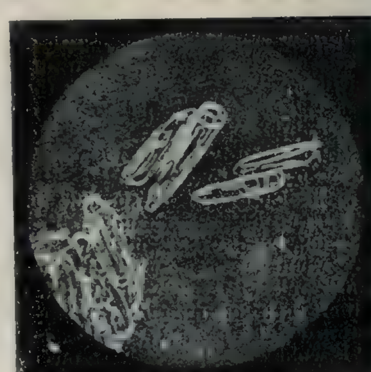

Fig 2.

[1] "Geol. Foren. i Stockh." Forh. Bd. 15, p. 146.

contain water in which one could sometimes (as in Fig. 2) *discern a small air-bubble*. On the day when this snowfall occurred the temperature was −8° C. Still there was a continual dripping of water from the house roofs, in spite of the fact that the sky was overcast, and the sun thus could not contribute to melt the snow. The dripping continued even at midnight in a temperature of −12° C. Shortly after the fall of snow a transformation could be observed in the crystals; on the surface of the snow they had passed from prismatic bottles to hexagonal tables *without any cavities*. The above described fall of small ice-bottles containing water, a phenomenon, as far as I know, new to meteorologists, combined with the transformation of the crystals after their descent, affords a simple explanation of the fact that, in spite of the severe cold, the new-fallen snow was so saturated with water as to cause an incessant dripping from the roof.

II. (*a*) *Hexagonal Tables*.

To the naked eye these crystals look like small, lustrous scales. Their dimensions vary between 0·8 and 1·4 mm. Under the microscope they prove to contain regular cavities, remarkable as being bounded not by planes, but, contrary to the accepted principles of crystallography, by *regularly distributed curved surfaces*. The limits of these cavities are shown under the microscope as fine black markings, to which, on account of their resemblance to forms within the organic world, I have applied the name of *organoid* lines, cavities, and formations. The following

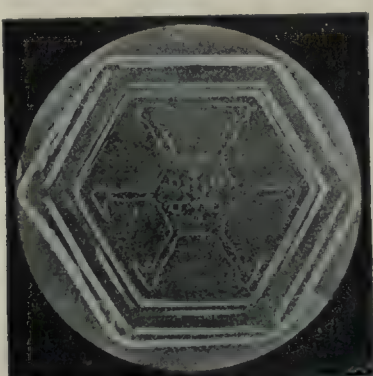

FIG. 3.

example will illustrate the structure of such crystals, including such organoid cavities. The snow-crystal (Fig. 3) shows in the centre a handsome star. The crystal is composed of two (or more?) superimposed tables, with the same orientation. The different hexagons indicate the outer limits of these tables. Two tables are united by a stratum, which has the outlines shown by the stellate figure. Within this figure the crystal is therefore homogeneous; without the same, its two different layers are separated by a flattened cavity, bounded by sinuate surfaces, and probably containing air. The same star includes some extremely regular cavities of smaller size. On this table we can observe a hemihedral development, the six triangular fields into which the hexagon is divided by lines drawn between the centre, and the angles being only alternately equal to each other. Such a hemihedry is the rule in this type. It is most developed in some almost triangular tables that occur among the equilateral hexagons. The above described structure, two tables united by a stellate layer of ice, is the general rule in the tabular ice crystals.

The organoid figures show a great multiplicity of forms, but the fundamental type is the same in all of them. It is evident that their outlines are fixed by certain crystallographic laws yet unknown to us. We might possibly find in these organoid formations, which so strongly remind us of shapes in the world of life, a clue to the mathematical laws of the structural outlines of organisms. Or perhaps these remarkable organoid figures are caused by microscopical aërozoic organisms, around which the crystals have developed. I hope next winter to be able to collect observations for the answering of this question

II. (*b*) *Stellate Tables*.

Figs. 4–6 show some of the countless modifications exhibited by crystals of this type. The central table often shows beautiful organoid figures sometimes hemihedrally developed and regularly orientated cavities. Similar

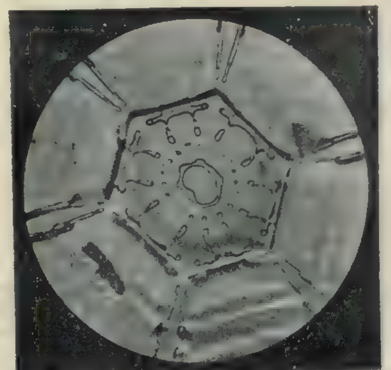

FIG. 4.

cavities, usually of very minute size, are with great regularity distributed in the arms of the star.

The ramification of the plates has some connection or other with the orientated cavities. Through each arm of the six-sided star runs what may be called the *main nerve*, which originates either in the central plate or just outside it. This nerve is present in all the tables and dendritic stars with elongated arms. The main nerve is bounded by two fine, parallel *gas canals*.

The first beginning of these canals consists of two or

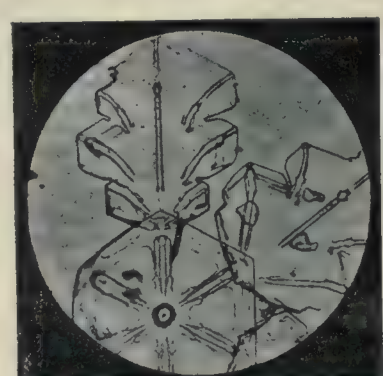

FIG. 5.

four small cavities with parallel orientation. In the continuation of these small cavities lie larger ones, often prolongated to extended canals (see Fig. 4). Owing to evaporation on the surface of the crystal, these canals gradually become open, first at one end, and then along a part or the whole of their extent, only the ridge that divides them remaining as a *nerve* (Fig. 5). That these canals are really cavities in the ice I have ascertained by observing and photographing snow crystals in a coloured liquid.

I found that the liquid gradually penetrated into and filled the canals which were open. Fig. 4 shows the central parts of crystals with canals partly filled with the coloured liquid. Near the centre small air-bubbles are still visible. Fig. 6 is the central part of a star powerfully magnified. The interesting structure may be judged by the photograph.

Phenomena attending the Compression of Snow Crystals.—A stellate plate was slowly compressed by screwing down the objective upon the cover-glass. After this pressure it was still entire. In the interior of the crystal *new curvilinear figures or pressure lines had appeared*, following a regular course analogous to that of the organoid figures. This analogy suggests that the latter may possibly be explained as tensional phenomena.

Exceptional Symmetrical Conditions.—The fine cavities in the centre of the stars are sometimes regularly ar-

FIG. 6.

ranged after only *two* symmetrical planes at right angles to each other and of different value (see Fig. 4), in accordance with the symmetrical conditions that we find in crystals belonging to the orthorhombic system.

Hoar-frost.—In addition to the photographing of snow crystals, I have also examined and reproduced by photography crystals of hoar-frost deposited on window-panes. Even these crystals formed often hexagonal tables, but were entirely without the remarkable cavities observed in snowflakes.

The investigations of which I have here given a brief account show that the structure of snow crystals is very complicated, and display several peculiarities which, so far as we know at present, are unexampled in other crystals. I hope to be able to resume these investigations next winter on a more extensive scale, in order to obtain, if possible, a complete elucidation of the interesting phenomena alluded to in the present paper.

G. NORDENSKIÖLD.

BÜTSCHLI'S ARTIFICIAL AMŒBÆ.[1]

PROF. BÜTSCHLI, of Heidelberg, so well known by his valuable work on the Protozoa, and his contributions to Bronn's "Klassen und Ordnungen," has, in the monograph under review, approached a subject of deep interest and great difficulty, namely, the cause of protoplasmic movement. His researches in this direction are already known to readers of the *Quarterly Journal of Microscopical Science*, for in 1890 Prof. Lankester inserted a letter from Prof. Bütschli, in which the latter gave a short account of his experiments. In the present monograph his researches are given in a completed form and in great detail. The gist of the whole subject may be put as follows:—Prof. Bütschli makes an artificial oil and water emulsion in a way suggested by Nuincke, and finds that under certain conditions drops of this emulsion exhibit streaming movements and changes of shape: according to Prof. Bütschli, protoplasm is itself a natural emulsion, and the streaming and amœboid movements of protoplasm are, like those of the artificial emulsion, due to surface tension.

Working at emulsions, Nuincke had previously found that if substances soluble in water be finely powdered and rubbed up with oil, and the oil subsequently surrounded with water, the latter diffuses into the oil, which it converts into a foam or emulsion of little water droplets closely packed together in the oily matrix. The emulsion may obviously be compared with the sea-foam, in which we find air globules closely packed in a water matrix, the oil in the emulsion and the water in the sea-foam having an alveolar or honeycomb build or form. The Nuincke emulsion is obviously, too, the reverse of the emulsions made by Johannes Gad with weak K_2CO_3 and oil, in which the oil droplets lie closely packed in a water matrix; it is also the reverse of the numerous emulsions made every day by the druggist who uses oil in mucilage, malt-extract, &c. When Bütschli first tried the Nuincke method he used common salt, sugar, and nitre, taking these as examples of substances readily soluble in water. He succeeded, however, better by using Na_2CO_3, or K_2CO_3, and proceeded as follows. The salt, preferably K_2CO_3, was obtained pure and dry, and was finely powdered in an agate mortar. He then breathed upon it until it was slightly moist, and rubbed it up with olive oil until a thick white paste was formed. A tiny drop of the paste was then placed on the centre of a cover-glass, and inverted over a drop of water, and in order that the drop might not be pressed out of shape by the weight of the cover, the latter was supported by little pellets of wax or paraffin. The preparations so obtained were placed on one side in a damp chamber for twenty-four hours, and then washed out with water by inserting a piece of blotting-paper into the chink between the slide and cover, and supplying fresh water at the opposite side of the cover by means of a pipette. The water was then replaced by equal parts of glycerine and water, after which the drops of emulsion became clear and transparent, exhibiting changes in shape and streaming movements very much like those of an amœba. It appears that the consistency of the olive oil is a very important factor in determining the successful issue of one of these experiments. Ordinary oil is of no use, it must be kept for some time in an open vessel, though the time may be shortened by keeping it in a hot-air chamber at 50°C. and testing the oil from day to day. It must be thick and viscous, but not too much so.

When examined by the aid of a microscope the emulsion appears as a network of oil enclosing the water droplets, for the structure is, of course, seen in optical section. Curious streaming movements may be observed within the emulsion, and these may continue for hours; movements of the drop as a whole occur, and always in the direction of the stream. If the emulsion drop be carefully watched it will be seen to change its shape, and to throw out processes—which, by the way, are always club-shaped—and to withdraw others. Up the centre of these processes a streaming movement takes place, and the streams at the tops of the processes spread out and flow back in a layer next the surface. These movements are influenced by warmth and electricity, and we have, therefore, in these Bütschli's drops something which might deceive one into supposing that actual amœbæ were in the field of observation.

The movements of the oil emulsion are due, no doubt, to changes in the surface tension of the fluids in contact with each other, Bütschli's case being an illustration of

[1] "Untersuchungen über mikroskopische Schäume und das Protoplasma." Von O. Bütschli. (Leipzig: Wilhelm Engelmann, 1892.)

the effects of surface tension, effects which are more simply shown in the contracting films, and tears of wine of the laboratory and dinner-party. It is well known that surface tension is capable of producing important and curious changes in the form of fluids, and will induce well-defined movements of a streaming character; surface tension, and the movements resulting from it, are modified and influenced by heat and electricity, and many biologists have suggested that surface tension may play an important part in producing amœboid movement. Prof. Bütschli takes many steps in advance of this; for having formed his artificial emulsion, he sees in all living protoplasm nothing but a similarly constructed emulsion, and concludes that because it is so similar its movements must be of the same nature. We feel in reading his work that not only does he in his enthusiasm twist the appearances of protoplasm to suit his own especial view of what its structure must be, but he is guilty of want of logical treatment of his premises when he has got them. Frommann, Hertzmann, Klein, and, indeed, most histologists regard protoplasm as consisting of a network of less fluid material, the interstices of which network are filled with a more fluid material, and this structure has been demonstrated in almost every animal cell. This view of the nature of protoplasm is open, however, we think, to criticism, for histologists are in the habit of preserving and hardening their tissues in fluids such as alcohol, picric acid, corrosive sublimate, which act as precipitants to protoplasm, and they blindly conclude that what they see in these preparations are present in the living cells. On this account many have questioned whether these networks are ever present in the living cells, and Berthold and Bütschli view living protoplasm as an emulsion of two fluids, one forming an alveolar honeycomb, the other filling its cavities. This honeycombed structure—emulsion—Bütschli finds everywhere, from the protoplasm of the protozoa to that of the higher vertebrates; where there was once a network now there is an emulsion. The interfibular substance of muscle mistaken by a few observers for a network is, for Bütschli, a honeycomb with frequent transverse partitions, and the fibrillated axis cylinder of a nerve has cross strands indicating that this is a honeycomb too. In the apparently structureless protoplasm of the outer part of an amœboid cell, such as is figured by Schäfer in the last edition of "Quain's Anatomy," this structure is present to Bütschli, and as he cannot see it there, even with the eye of faith, it is believed to be too delicate and the meshes too finely drawn out to be seen.

As to the chemical nature of protoplasm, about which most biologists who have had anything of a chemical training feel themselves rather in the dark, Prof. Bütschli has fairly definite views, and these it must be admitted fit in admirably with the emulsion theory. The honeycomb he regards with Reinke as a nucleo-albumen, containing some molecules of a fatty acid, and not miscible with water; the more fluid portion of protoplasm, filling the interstices of the honeycomb, he regards as a watery fluid containing albumen and an alkali free or combined with it.

Holding the above views concerning the structure of protoplasm, which indeed, according to Bütschli, resembles both in minute anatomical structure and chemical and physical properties the microscopic froth which he can manufacture, he looks upon the cause of the movements of the froth as the cause of the movements of the amœba, and also in all probability of striped muscle itself. Let Prof. Bütschli speak for himself:—

"Die Bewegung einfacher Amöben, wie A. guttula, limax, A. blattæ, Pelomyxa, ist den früher beschriebenen strömenden Oelseifenschaumtropfen so ungemein ähnlich, ja in allen wichtigen Punkten, so ganz ihr Ebenbild, dass ich von der Uebereinstimmung der wirksamen Kräfte in beiden Fällen vollkommen überzeugt bin" (page 198, see also pages 200 and 208.)

Now, for some time past it has been held that surface tension plays a part both in the streaming movements of protoplasm and in the production of amœboid movement, but no one has pushed this idea to the extent that Bütschli has done. Let us see if the facts of the case justify him in so doing. It is true that the picture of the moving foam and of the moving protoplasmic mass present many points of similarity to the eye of the observer, but what of that? The waxwork figure may deceive us all into imagining that it is a man, but once we know what it is the most ignorant of us would hardly venture to argue from its mechanism to our own. So when we look at Bütschli's foam particles, and when we are told that they do not consist of protoplasm, and merely of rancid olive oil and a weak carbonate of potash, then we may exclaim at their interest and novelty, but we shall not seriously compare them with living protoplasm. Science is passing through two phases—the first spiritualistic, the second mechanical. Psychology is still very much in the first stage, and physiology in the second. There are still those among us to whom the circulation is a thing of tubes and force-pumps, and nothing more, and absorption a process that can be imitated by a parchment dialyzer. Fortunately, we are getting rapidly through these two stages, and are beginning to recognise that the force-pump and parchment paper have led us often into wrong conclusions. Studies in evolution have taught us that protoplasm, made up no doubt of elements of the inorganic world, is nevertheless a complex of these elements of unique character, and with properties distinct from everything that is not protoplasm. The oil emulsion may, to the eye of the observer, conduct itself in a way exactly similar to an amœba—which, by the way, it does not, its processes being club-shaped, and never pointed—but this does not indicate that amœboid movements are similar in their nature. With equal right would the to-day representative of Madame Tussaud urge, on the strength of their waxwork show, that human arms move by springs and clockwork. Not only do these foam particles tell us nothing about protoplasm, but for the investigation of questions of surface tension they are evidently ill fitted. They are toys for the physicist, not for the physiologist. We know that surface tension can well account both for changes in shape and flowing movements of fluids; it is only by experimenting on protoplasm itself that it will be possible to determine what part this agency plays in protoplasmic activity.

In Professor Bütschli's work the reader will find much valuable information as to the views held from time to time as to the structure of protoplasm; and the production of this monograph is a strong indication of the single-mindedness both of German scientific men and of German publishers. It is a large quarto volume of two hundred and thirty pages, well printed, and illustrated with six beautiful plates, and upon a subject which of necessity appeals to a very limited number of readers.

JOHN BERRY HAYCRAFT.

FINGER-PRINTS IN THE INDIAN ARMY.

IT may interest some of your readers to see the terms of the order by which the method of finger-prints for purposes of identification has now been introduced into the Indian Army. A copy of it, sent by Lieut.-Colonel Surgeon Hendley, of Jeypore, has just reached me.

Army Headquarters, Medical Division, Simla, August 25, 1893.

In continuation of this Office Circular, No. 5, dated January 16, 1891, it is requested that as a means of identification of recruits for the Native Army, examining medical officers will cause an impression in printer's ink of the ends of the first three fingers of the right hand of each recruit passed by them as fit for the service, to be made on the Nominal Roll opposite the name of the recruit; and in the case of the Army Hospital Corps, in the Verification Roll.

A specimen of the required impression is shown below.

By order.

(Signed) C. H. Pearson, Surgeon-Major,
Secretary to the P.M.O., H.M.'s Forces in India.

[Here follows the specimen impression.]

I trust that the medical officers who will have to take these prints, understand the importance of using so little ink that the impression shall be *clear*, though its tint may be only brown and not black; also that when comparing two prints they will use a low power lens and four pointers, two for each print. I have lately been using a watchmaker's glass of two-inch focus, secured to the end of a long and counterpoised arm, which turns, not too easily, round the screw by which it is attached to its support. The lens can be brought into focus with great ease, and it remains steady when left alone. I use at least two pointers for each print. They are T-shaped; their long arms are six or seven inches long, they are roughly made of wood as thick as the thumb, so that they are purposely not over light. Each pointer stands on three supports, viz. on the point of a bent pin, whose headless body has been thrust into the end of the long arm of the T, and on the ends of two nails, or better on staples, one of which is driven under either end of the cross-arm. It is most easy to adjust the point of the bent pin upon any desired character in the finger-print. Both hands of the observer are thus left free to manipulate other pointers, when desired. The stationary pointers are a great help in steadying the eye while pursuing a step by step comparison between two finger-prints.

Francis Galton.

NOTES.

The collected works of Jean Servais Stas, which it is proposed to publish as a mark of honour to his memory, form three quarto volumes of about 500 or 600 pages each. The first volume contains the memoirs and papers relating particularly to the determination of atomic weights; the second comprises notes, reports, and lectures; and the third, posthumous works, which especially refer to spectroscopic researches. The edition is under the direction of MM. Spring and Defaire, and it will probably be completed in about a year. The three volumes will be published simultaneously at the uniform price of thirty francs. Subscribers of twenty francs or more to the Stas memorial fund will each receive a copy of the work, and contributors of less than twenty francs may increase their contributions to that sum, and so become a recipient. The names of subscribers will be published in an appendix to the third volume. After the completion of publication, the balance of the fund will be used for the erection of a monument. Stas' scientific work is more than sufficient to perpetuate his name among men of science, and the monument which it is proposed to erect will make it "known to all people."

At the second day's meeting of the Photographic Congress, the opening of which was noted in our last issue, Mr. Andrew Pringle read a paper on "The Present Position of Micro-Photography," and W. Weissenberger contributed one on "A Process of Photo-Mechanical Printing in Natural Colours." The president, Capt. Abney, read a paper dealing with "Exposure and Chemical Action," in which he showed that the sum of excessively small exposures is not equivalent to the same exposure given at one time, and further, that very feeble intensity of light fails to produce the calculated amount of chemical action. Capt. R. H. Hills followed with a description of the instruments employed and the results obtained during the recent solar eclipse. At the final meeting of the congress, on October 12, Dr. A. Miethe read a paper on "The Practical Testing of Photographic Objectives," and Dr. P. Rudolph one on "The Measure and Numeration of the Stops of Photographic Lenses."

A statue of Duhamel-Dumonceau was unveiled at Pithiviers, on October 1. The French Minister of Agriculture, who performed the ceremony, claimed that Dumonceau was the first to institute agricultural experiments in the field.

Dr. H. Möller has been appointed Professor of Botany in the University of Greifswald.

At the meeting of the International Geodetic Association, recently held at Geneva, a Commission, composed of M. Tisserand, with Profs. Foerster and Schiaparelli, was appointed to draw up a programme of observations to be made permanently at a number of different places in order to elucidate the question of latitudinal variations. The association will hold its annual meeting in Austria next year.

The *Lancet* says that the Apothecaries' Society are about to apply to the courts for powers to sell their Botanical Gardens at Chelsea, the money value of which has been fixed at about £30,000. The removal of this historic garden would be a source of keen regret to the many who have profited by the instruction conveyed by its means.

We are informed that the fund raised for paying the costs of Dr. Wallis Budge in the recent action of Rassam *v.* Budge has been fully subscribed. The list of the contributors, which is too long to print in its entirety, includes the following names:—Miss H. M. Adair, the Duke of Argyll, K.G., K.T., Lord Armstrong, C.B., the Marquis of Bath, Walter Besant, Dr. C. Bezold, Rev. H. Blunt, E. A. Bond, C.B., the Earl Cadogan, K.G., the Earl of Carlisle, Somers Clarke, N. G. Clayton, Miss Clendinning, Alfred Cock, Messrs. Thos. Cook and Son, Sir John Evans, K.C.B., F.R.S., Sir W. H. Flower, K.C.B., F.R.S., C. Drury Fortnum, A. W. Franks, C.B., F.R.S., Right Hon. W. E. Gladstone, M.P., Rev. Canon Greenwell F.R.S., Major-General Sir F. Grenfell, G.C.M.G., K.C.B., H. Rider Haggard, Lawrence Harrison, Thomas Harrison, James Hilton, Thomas Hodgkin, Sir H. H. Howorth, K.C.I.E., M.P., F.R.S., Right Hon. Thomas Huxley, F.R.S., Sir Frederick Leighton, Bart., P.R.A., William Lethbridge, Rev. W. J. Loftie, Right Hon. Sir John Lubbock, Bart., M.P., F.R.S., Lady Meux, F. D. Mocatta, Walter Morrison, Sir Frank Mowatt, K.C.B., Sir Charles Nicholson, Bart., D.C.L., the Duke of Northumberland, K.G., F. G. Hilton Price, Hon. W. F. D. Smith, M.P., E. Maunde Thompson, C.B., Cecil Torr, Sir Reginald Welby, G.C.B., John White.

New and extensive electrical works were inaugurated at Blackpool at the end of last week. In the course of a speech made during the celebrations, Lord Kelvin expressed the opinion that municipal corporations were right to take into their hands everything calculated to further the general good of the borough. It seemed to him that the Government ought to take up the whole business of telegraphs and telephones, and it would not be an improper thing if the whole railway system of the country were placed under the same management.

An International Congress on Aerial Navigation formed one of the series of congresses which have recently been held at Chicago. The papers read on that occasion are being published in the form of a supplement to the *American Engineer*, together with other information relating to aeronautical engineering. The new publication is given a distinctive title, *Aeronautics*, but whether it will be continued after the whole of the proceedings of the aeronautical conference have been issued will depend upon the success of the enterprise.

The first International Botanical Congress ever convened on American soil was held at Madison, Wis., immediately after the adjournment of the American Association for the Advancement of Science, August 23 and 24. The foreign representation, however, was so small that the title of the meeting was changed to the "Madison Botanical Congress." The meeting was an outgrowth of that at Genoa last year. Prof. E. L. Greene, of California, was elected president. All the subjects discussed at the meeting referred to terminology, the following being the topics:—(1) Plant diseases; (2) anatomy and morphology; (3) physiology; (4) horticultural forms; (5) bibliography. It is expected that the next meeting will be held in Europe in 1894, but the precise time and place was not announced.

That Traugott Friedrich Kützing, the author of the *Phycologia generalis*, should have been still with us until within the last few weeks will probably be a surprise to many. As an author, Kützing had indeed completely disappeared from the scientific world; he had published nothing for more than twenty years, and nearly all his most important works appeared before the close of the first half of the present century. He may indeed be regarded as the founder of a scientific study of the Algæ, especially of sea-weeds. Much of his work has, of course, been superseded by more recent investigations; but his *Phycologia generalis*, published in 1843, his *Tabulæ Phycologicæ*, issued in twenty volumes from 1845 to 1870, with 2000 illustrations, and his *Species Algarum*, 1849, are still classical works, which must needs be in the hands of every student of the lower forms of vegetable life, if it is only for the excellence and life-likeness of their illustrations. In 1841 he published the *Umwandlung niedrer Algenformen in höhere*, and in 1844 the *Die kieselschaligen Bacillarien oder Diatomen*, the introduction to our knowledge of the structure of the diatom-shell, in which there is now so extensive a literature. Kützing died on September 9, at Nordhausen, in the 87th year of his age. His extensive collection of dried Algæ has long been in the possession of the University of Leyden.

Mr. G. W. Young has issued "A Key-table showing the characteristics of the principal Natural Orders of the British Flora," compiled for the use of students. A very brief synopsis is given of the leading characters of each natural order, and a familiar plant is mentioned as a "type." A few small corrections might be made in a subsequent edition. Thus, *Dielytra spectabilis* is the gardener's, not the scientific, name of the plant indicated; in the Caryophyllaceæ the "free central placentation" is by no means universal.

Few geographers of the present day enjoy so wide a reputation as Baron F. von Richthofen, Professor of Geography in Berlin University, and it is pleasant to observe the fitting way in which his former students did honour to the sixtieth anniversary of his birth on May 5, 1893. Many of them wrote papers, either on geographical or geological subjects, for special publication in the form of a handsome book, "Festschrift," bearing Baron von Richthofen's portrait as frontispiece. Among the contributors we note the names of A. Philippson, F. Frech, H. Yule Oldham, C. E. M. Rohrbach, and E. Hahn.

Dr. A. Philippson's contribution to the "Festschrift" is an interesting investigation of the "Types of Sea-coasts" (Ueber die Typen der Küstenformen). Dr. Philippson insists upon the study of the simplest types of form and the individual relationship of these types to the groups of natural agents which produce them. He shows how all sea-coasts may be reduced to two great and fundamental types. (1) Isohypsal coasts, where the existing form of the coast-line still coincides with the primary relief of the earth's surface at that part, so that we may trace its origin from tektonic, volcanic, or other earth movements. (2) Thalassogenic coasts, where the primary isohypsal condition of the coast-line has been in greater or less degree obliterated by the action of "littoral forces." Dr. Philippson gives particular prominence to the flat-beach variety of thalassogenic coasts, and describes in detail the purely potamogenic type due to the action of inflowing rivers, the purely thalassogenic type due to the action of breakers, and to the building-up and breaking-down of "strand-walls." Lastly, the mixed potamogenic and thalassogenic type combining the characteristics of both. Numerous examples are drawn from familiar European coast-lines, and several diagrams are given.

A paper on "The Mechanical Genesis of the Form of the Fowl's Egg," was read before the American Philosophical Society on April 21. In it Dr. J. A. Ryder gives evidence that the configuration of the outline of the hen's egg is determined by mechanical means while the egg membranes and shell are in the process of formation within the oviduct. "The pressure preventing the passage of the elliptical mass down through an elastic tube must be developed largely in the form of friction, and the resistance of the walls of the oviduct to dilation. To overcome this a greater pressure must be exerted on the elliptical egg-mass at a point above its minor axis than below the latter. This will tend to squeeze part of its substance, since it is at last enclosed in an elastic capsule before shell-formation takes place, into the lower or larger end of the mass. In this way the ovoidal form of the egg seems to have first arisen." It therefore appears that the development of the figure of the eggs of birds is a purely dynamical problem, or one in which energy is applied in a definite manner to the plastic surface of a mass in statical equilibrium within the oviduct. This principle has many extensive applications, and may lead to the elucidation of several obscure points connected not only with the eggs of birds, but also those of reptiles and insects.

In a letter to *Science* for September 15, Mr. O. T. Mason relates the discovery at the World's Columbian Exposition of two examples of the Mexican atlatl, or throwing-stick, lying in the Colorado Alcove. His description is as follows:—The shaft is a segment of a sapling of hard wood. At the distal end is a shallow gutter and a hook to receive the end of a spear-shaft. At the proximal end or grip in the more perfect specimen, about four inches from the extremity, is a loop on either side of the stick, one for the thumb, the other for the forefinger. The remaining three fingers would be free to manipulate the spear-shaft. These loops were made by splitting a bit of raw hide, sliding it down the proper distance on the stick, forming loops less than an inch in diameter by bringing the projecting ends of the raw hide, and seizing it fast to the shaft. Below the finger-loops or stirrups were a long chalcedony knife or arrow-blade, the tooth of a lion, and a concretion of hematite seized by a plentiful wrapping of yucca cord. Mr. Mason believes that the Bourke example from Lake Patzcuaro belongs also to the same outfit. This is the first instance, as he says, of "finding the ancient atlatl figured in the codices, and described by Mrs. Nuttall." A connection between the cliff dwellers and the Mexican peoples is thus indicated.

Dr. G. Schott contributes to a recent number of *Globus* an account of the Atlas of the Indian Ocean, published by the *Deutsche Seewarte*, with particular reference to the behaviour of the storms of the tropical part of that ocean. The article plainly shows that whereas some twenty years ago the Germans were dependent on the labours of English seamen for their sailing directions, they now rely almost entirely on their own publications, except as regards nautical charts. Dr. Schott gives an intelligible account of the older or circular theory of storms, and of the later, or spiral theory, to which attention was drawn by Dr. Meldrum, in 1860. If the former theory be correct, a ship which in a given position might safely run across the path of an advancing storm, would according to the later theory run into the most dangerous part of it. Between these theories seamen must therefore have great difficulty in shaping a correct course at the most critical time, and every careful investigation into the movements and laws of storms should be welcomed, in the interest of science, whether undertaken by this country or by foreign nations.

IN connection with the science meetings at the Chicago Exhibition, Dr. M. A. Veeder read a paper on periodic and non-periodic fluctuations in the latitude of storm tracks, in which he referred to the occasional rearrangements in the distribution of the atmosphere, consisting, in the main, in the displacement of the belts of high pressure on each side of the equator, with the consequent deflection northward or southward of the usual courses taken by storms. Notable instances of this kind have occurred at different times, such as in 1877–8 and in 1888–9, and the present year also affords another example, the winter in northern latitudes being distinguished by a severity in strong contrast to their mildness during the years above mentioned. These rearrangements of weather conditions on a large scale make it difficult, the author considers, to resist the conclusion that the atmosphere as a whole is under the control of forces which have a common origin, and depending upon some form of solar variability. Although it is not yet beyond dispute whether the sun is hottest or coldest when most free from spots, the evidence appears conclusive that the weather conditions in question bear some sort of relation to the spottedness of the sun. The author thinks that there is ground for the belief that there may be special forms of solar activity not yet fully understood, which exercise powerful terrestrial effects independently of the amount of solar heat falling upon the earth as a whole, and which may be of the nature of electro-magnetic induction, and depend upon conditions different from those which appear in the case of simple radiation from a source of combustion. If the variation in weather types follow the solar electro-magnetic record, he thinks that it would not be unwise to approach the problems from this side of the question, although it would involve a reconsideration of the facts of meteorological science from a standpoint different from that of an assumed variability of solar heat. The author considers that it may be necessary o discard provisionally the accepted theory of the origin of storms, in order to determine the part which electro-magnetic induction of solar origin plays, independently of heating effects. In any case, the study of periodic and non-periodic fluctuations in latitude of the cyclonic and anti-cyclonic belts surrounding the earth is most important in many ways.

A CONVENIENT modification of the hydrometer method of determining the densities of gases has been devised by M. Meslans, whose apparatus is described and illustrated in the *Comptes rendus*, No. 11. It consists of two hollow spheres hung to the arms of a balance. Each sphere, which is made of glass, aluminium, or gilt copper, hangs in a separate compartment, the suspending thread being introduced through a hole in the lid. The compartments are enclosed in a box and surrounded by water in order to keep them at equal temperatures. They are at first filled with air to determine the position of equilibrium. The gas whose density is to be determined is then introduced through a long tube immersed in the water, and enters one of the compartments, having previously been dried. The gas is passed through in a slow and continuous stream, and if its density differs from that of air, the equilibrium of the balance is disturbed. The weight necessary to re-establish equilibrium is noted, and the density calculated according to a simple formula. Thus the density is found by a single weighing, and by keeping the current of gas continuous any variation in its density is easily observed. A fairly high accuracy is attainable, depending upon the sensitiveness of the balance and upon the perfection of gauge of the spheres. One important application of the apparatus is that for determining the density and composition of the products of combustion in furnaces. The scale of the balance is graduated so as to show at a glance the percentage of carbonic acid, and hence the degree of efficiency of the furnace in question. This percentage, which is 21 theoretically, never exceeds 18 in practice, except in gas generators. In a great number of works it varies between 6 and 8. M. Meslans' apparatus is being applied to the study of the various methods of heating. Another application is that by which the presence and percentage of marsh-gas is indicated. With spheres of 1 litre capacity and a balance sensitive down to half a milligramme it was found possible to detect 0·1 per cent. of methane in the air of a mine.

THE *Electrical Review*, in the course of an article on "Electrical Engineering at the World's Fair," describes the curious rotary effects of a two-phase alternating-current field-magnet. A ring-armature is wound with four coils, connected in pairs across the circle; one pair is connected to one of the two-phase currents, the other pair to the second current. The ring-armature is then laid horizontally on a table, and a board placed over it. Almost any metallic article placed on the board immediately begins to run round above the ring. Copper balls, coins, &c., or any other easily movable conducting article will at once get into motion.

THE October number of *Mind* contains an article on theories of light-sensation, by Mr. C. L. Franklin.

MR. GEORGE HOGBEN has sent us two papers extracted from the Transactions of the New Zealand Institute, 1892, and referring to earthquakes experienced at the Antipodes in June, July, and December, 1891.

THE lecture on "The Interdependence of Abstract Science and Engineering," delivered by Dr. W. Anderson, F.R.S., at the Institution of Civil Engineers, in May last, has been extracted from the Proceedings of the institution, and is now published separately.

A COURSE of lectures upon Planetary Astronomy, with especial reference to "The Planet Venus" will be delivered in the theatre of Gresham College, on the evenings of October 24, 25, 26 and 27, by the Rev. E. Ledger.

A HANDY book on "The Art of Projection and Complete Magic Lantern Manual," by an expert, has been published by Mr. E. A. Beckett, Kingsland-road, N.E. Lantern operators will find in it many useful hints upon matters of manipulation.

MESSRS. WHITTAKER AND CO. have published the "Principles of Fitting," for apprentices in engineering and students in technical schools, by a Foreman Pattern Maker. The book is profusely illustrated, and should be of great assistance to the workers for whom it is intended.

STUDENTS preparing for the examination in the "Principles of Mining" held by the Department of Science and Art, or for colliery managers' examinations, are recommended to use an elementary text-book of "Coal Mining," by Mr. Robert Peel, just published by Messrs. Blackie and Son. The book is very well written and quite trustworthy.

A DAINTY brochure, by Martha F. Sesselberg, entitled "In Amazon Land," and containing adaptations from Brazilian writers, with original selections, has been published by Messrs. G. P. Putnam's Sons. The part of the book of interest to us refers to Amazonian legends, beliefs, traditions, and superstitions.

A SECOND edition of "An Introduction to Human Physiology," by Dr. A. D. Waller, F.R.S., has been published by Messrs. Longmans, Green and Co. Several alterations and transpositions of text have been made, and the results of many recent investigations have been included, thus giving additional value to an already highly appreciated work.

WE have received the Transactions of the Sanitary Institute, vol. xiii. The volume consists chiefly of reprints or abstracts of the papers read at the conferences which were organised in connection with the congress held at Portsmouth in 1892. It also includes an address to sanitary officers, delivered by Sir Douglas Galton at Worcester.

A CLASSIFIED list of plants in the Royal Botanic Gardens, Trinidad, has been issued as a *Bulletin of Miscellaneous Information*, No. 17, by Mr. J. H. Hart, the Superintendent. The list contains the names of plants under cultivation and indigenous in the Gardens, and is of scientific as well as economic interest.

DR. KICUCHI, of Tokyo, has just published, in Japanese, a text-book on Trigonometry, thus carrying on the good work he has begun in his manuals on Geometry, Logic, &c., and in his translations of "Clfford's Common-sense of the Exact Sciences," of "Russell's Technical Education," &c. The degree of Rigakuhakushi (= D.Sc.) is a degree conferred by the Minister of Education with the advice of the Council of the University.

LIEUT. J. P. FINLEY has prepared a report on "Certain Climatic Features of the Two Dakotas" for the U.S. Department of Agriculture. The report is illustrated with 163 tables, charts and diagrams, and it presents a vast amount of information concerning the meteorological phenomena which are believed to have a marked influence upon the agricultural interests of the States investigated. From the report it appears that the Dakotas should at once resort to an extensive system of irrigation in order to increase the precipitation and check the high evaporation. Forests ought also to be preserved, and extensive plantings of trees should be made. In the words of the report, "The meteorological and physical features of the Dakotas are such that, under the influence of settlement and the consequent development of agriculture, changes are effected which tend to the rapid dissipation of the moderate rainfall, through absorption and evaporation. Irrigation and reforestation are the only remedies."

THE disinfecting properties of peroxide of hydrogen have long been known, but considerable additions have been recently made to our more exact information concerning its bactericidal action. Richardson (*Chem. Soc. Journal*, Sept. 1893) has shown that the antiseptic action of sunlight on urine is due to the production of peroxide of hydrogen, for samples exposed to sunshine remained clear, and on examination were found to contain peroxide, whilst similar samples kept in the dark became turbid and contained no peroxide. Traugott, in "Einige Ergänzungen zur Praxis der Desinfection" (*Zeitschrift für Hygiene*, vol. xiv. 1893, p. 427), points out as the result of his investigations that this material may be substituted in all cases for corrosive sublimate and carbolic acid where the period of contact is not less than a quarter to half an hour; but that it is not suitable where rapid disinfection is required, as in the case of the disinfection of the hands, &c. Being innocuous and also harmless as regards clothing and the like, it is a safer disinfectant for general application than the former; its cost is, however, considerably greater. Some years ago, Heidenhain stated that he had constantly used peroxide of hydrogen as a gargle in cases of diphtheria, and Traugott mentions in his memoir that ten seconds' contact of a 2 per cent. solution of H_2O_2 with a young and vigorous growth of the diphtheria bacillus on blood serum, entirely destroyed this organism. If however two days' old cultures were similarly treated, contact for thirty minutes, even when repeated three times, was not sufficient for its annihilation. Thus the therapeutic value of this material consists in its immediate application at the very outset of the disease, whilst it may be recommended as an important prophylactic during epidemics of diphtheria.

AS regards the hygienic importance of peroxide of hydrogen, and its practical application, the experiments of Van Tromp and, later, Altehoefer on its action upon bacteria, pathogenic and otherwise, in water are of much interest. Van Tromp mentions that an addition of peroxide of hydrogen in the proportion of 1 : 10,000 parts of the water, when shaken up and allowed to stand for twenty-four hours, is usually sufficient to sterilise a water. Altehoefer, however, found that to ensure sterility it was advisable to use larger quantities, viz. 1 : 1000 parts of the water. Experiments made with waters purposely infected with cholera and typhoid bacilli, respectively, showed that in both cases these organisms were destroyed after twenty-four hours by this proportion of peroxide of hydrogen. Altehoefer, moreover, specially mentions that he found this addition in no way interfered with the dietetic value of the water, and recommends its application for household purposes as a protective measure during any epidemics of typhoid fever and cholera. Traugott also testifies to the innocuous character of this material even when swallowed in large doses, and states that 100 grm. or half a wineglassful of a 5 per cent. solution was administered by one of the doctors in a hospital in Breslau without any ill-effects whatever, whilst undoubted benefit was derived from its use. Care must, however, be taken that the particular material employed is as pure as possible, as traces of the poisonous barium chloride in larger or smaller quantities may be present; moreover, it is important that the sample should be freshly prepared, as its strength and consequently bactericidal action is reduced when it has been preserved for some time.

WE are indebted to *The Gas World* for the following particulars concerning a remarkable process, which is now being successfully worked, for very considerably increasing the illuminating power of coal gas, involving what at first sight would appear the highly dangerous operation of introducing into the gas a quantity of pure oxygen. In the year 1890 Mr. Edward Tatham, of New South Wales, made the bold proposal to add considerable quantities of pure oxygen to warm, heavy oil gas, with the object of producing a stable gas of very high illuminating power. Later in the same year Dr. L. T. Thorne communicated to the Gas Institute the results of preliminary experiments with this gas, which he had carried out on behalf of Brin's Oxygen Company. These experimental results led to the conclusion that rich oxy-oil gas *per se* was far and away more effective as an illuminant than the coal gas now employed for this purpose, but that its more immediate prospect of use lay in the direction of enhancing the lower illuminating power of ordinary coal gas. Preparations have since been made for practically testing the applicability of oxy-oil gas to the enrichment of coal gas, and the Hydro-Oxy Gas Patents Proprietary, Limited, have erected at 11, Salisbury-square, E.C., a complete experimental plant for the purpose. Moreover, the corporation of Huddersfield are erecting a plant for the purpose of enriching the coal gas supplied to the borough. The Huddersfield installation is not yet completed, but a portion of it is ready, and is now in actual operation. When complete it will consist of an oxygen plant and four bays of oil-gas retorts, capable collectively of producing 200,000 cubic feet of oxy-oil gas per day, together with the necessary condensers and holders. The oxygen plant has been already erected by Brin's Oxygen Company, and is their newest type of producer. It is built in two sections, which may be worked together or independently, and will make no less than 30,000 cubic feet of oxygen per day. This, the largest oxygen-producer ever constructed, is now in active operation. Of the oil gas plant one bay, consisting of fifteen cast iron retorts, is also working, and is capable of producing 50,000 cubic feet of oil gas per day. The lowest and hottest of the retorts are intended for "cracking" the residues from the upper retorts, but they may of course be fed with clean oil if required. The oxygen is introduced into the oil gas soon after the latter leaves the retorts and while still warm; the mixed gases then pass together through the condensers. The admission of the oxygen is automatically adjusted by means of a combination of meters, so that the proportion is constantly maintained at fifteen per cent. The oxy-oil gas is stored in special holders, and it is arranged to admit it into the coal gas just before the entry of the latter into the station meter, the quantity being regulated by a meter coupled to the station meter. The results so far attained are highly satisfactory. The admission of about six per cent. of oxy-oil gas is already found to increase the illuminating power of the corporation gas by the equivalent of five and a half candles, and this is probably much below the enrichment which will eventually be attained when the plant is complete, and when normal coal can again be employed at the cessation of the strike. The results attained by the Salisbury Square plant are considerably superior to this, and it is expected that the Huddersfield installation will eventually attain the same standard. Further, a marked increase in the stability of the gas is observed, for poor coal gas actually loses more illuminating power by storage than the same gas admixed with oxy-oil gas does. As regards cost, it is calculated from the experimental data furnished by the working portion of the Huddersfield installation, that the increased cost of production of the gas so enriched will not, at the highest estimate, exceed a third of a penny per thousand cubic feet.

Notes from the Marine Biological Station, Plymouth.—Last week, like its immediate predecessors, was characterised by stormy weather, which confined the dredging operations to inshore areas. The chief capture was a large haul of the Opisthobranch *Oscanius* (*Pleurobranchus*) *membranaceus*. The approach of winter is already indicated in the bottom fauna: colonies of the Compound Ascidian *Fragarium elegans* have been frequently taken in their state of "hibernation," and the colonies of the Polyzoan *Bugula turbinata*, which in the summer orms extensive forests on the stones in certain areas, have now almost completely died down. The Nemertine *Amphiporus dissimulans* has begun to breed, and the greater number of *Micrura fasciolata* are full-grown and sexually mature.

The additions to the Zoological Society's Gardens during the past week include two Sykes's Monkeys (*Cercopithecus lbigularis*, ♀ ♀) from West Africa, presented by Mr. W. H. Barber; a Thick-furred Capuchin (*Cebus vellerosus*) from South America, presented by Mr. R. Kettle; three Tigers (*Felis tigris*, ♂ ♀ ♀) from India, presented by H.R.H. Princess Beatrice; a Senegal Parrot (*Pœocephalus senegalus*) from West Africa, presented by Mrs. Rylands; a Ruddy-headed Goose *ernicla rubidiceps*, ♂) from the Falkland Islands, presented y Mr. Henry Phillips; a Tuatera Lizard (*Sphenodon punctus*) from New Zealand, presented by Mr. C. Stonham, F.Z.S.; a Diamond Snake (*Morelia spilotes*) from New South Wales, presented by Mr. Arthur W. Darker; a White-fronted Lemur (*Lemur albifrons*) from Madagascar, two Common Squirrels (*Sciurus vulgaris, albino*) British, deposited; two Blue-winged Teal (*Querquedula cyanoptera*) from South America, a Japanese Teal (*Querquedula formosa*) from North-east Asia, a Himalayan Monaul (*Lophophorus impeyanus*) from the Himalayas, a Turnstone (*Strepsilas interpres*), a Curlew (*Numenius arquata*) European, purchased; a Molucca Deer (*Cervus moluccensis*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

The Scintillation of Stars.—Though the question as to the cause of the scintillation of stars has not received the attention of many workers, yet it has had and still retains its adherents. In a recent number of the *Revue Scientifique*, M. Dufour gives the results of observations commenced in the year 1853. The observations were made with the naked eye, and were continued in all seasons and in all conditions of the weather, since the chief object of the investigation was to find out whether there was any relation between the scintillations of stars and the disturbances which occur in our atmosphere. The first results which were obtained led to the forming of the following laws. (1) That red stars scintillate less than white stars. (2) The intensity of the scintillation is nearly proportional to the product obtained by multiplying the astronomical refraction for the height at which the star appears, by the thickness of the stratum of air traversed by the luminous ray that one is considering, and (3) that the causes of some of the essential differences between the scintillations of different stars may perhaps be due to the stars themselves. Experiments for studying the question as to whether there was any difference between the scintillation on mountains and upon the plain, showed that on the mountains the scintillation was most feeble. An important meteorological conclusion, which, as M. Dufour says, is contrary to general opinion, and which he deduces from his numerous observations, is that a feeble scintillation generally announces the approach of bad weather. He gives many instances in support of his view, among which occur the observations at Col du Géant on July 12, 1788, when the brightest stars in Lyra, Cygnus, and the Eagle at the same altitude showed practically no signs of scintillating, while the next day there broke out over France the most violent storm that the annals of meteorology had ever registered. M. Dufour compares his work with that of M. Montigny, who commenced work after him, and who was led to the same three laws above mentioned. He suggests that as his observations were made in Switzerland, it would be interesting to find out if a feebleness of scintillation observed at sea also indicates bad weather.

A Universal Telescope Stand.—The construction of a good and simple universal mounting for small telescopes has been the aim of many instrument makers, and it is pleasing to note an advance in this direction made by the firm of K. Fritsch, formerly Prokesch, in Vienna. In their new so-called "*Universal statio*" they have overcome many of the main difficulties. The chief point about this special kind of mounting is that the observer can either use the telescope as a theodolite—that is, with circles reading altitude and azimuth—or, by a slight adjustment, he may have the equatorial mounting where the circles read right ascension and declination. This end is gained by hinging what would be the polar axis on to a pivot at the side of the stand, thus allowing the axis to be moved from the horizontal to the vertical or any intermediate position. A strong metallic arc fixed on the top of the stand supplies a means of clamping this axis, and giving it a slight adjustment. With the axis vertical, we have then practically a theodolite mounting; with the axis out of the vertical, a parallactic mounting. It is needless to say that this mounting is only for small telescopes, and indeed its application to large ones is not needed. A detailed account of the mounting, with figures, will be found in No. 208 of *Prometheus*.

Popular Astronomy.—Some time ago we inserted a note in this column to the effect that the editors of *Astronomy and Astro-Physics*, if they received sufficient support, would publish a monthly journal—*Popular Astronomy*—written especially for the rapidly increasing number of amateurs. We are glad to say that we have recently received the first (September) number, and, as far as one can judge, the journal has a successful future before it. The present number contains the first chapters of some series of articles on various subjects. To give some idea of the subject-matter and their writers, we may mention that "The Spectroscope, and some of its applications," is dealt with by Keeler; "Concerted Observation of the Aurora," by Veeder; "Shooting Stars: How to observe them, and what they teach us," by Denning; "Nebulæ and Comet-seeking," by Lewis Swift; "The Moon," by W. W. Payne, &c.; while future numbers will contain a series of articles by Barnard, on "Celestial Photography"; one by Elgar, on "The Moon"; another by Hale, on "The Sun," and many others. The treatment of the subjects is all that could be desired for those not acquainted with technicalities, and the illustrations, which include two excellent ones of the moon, are of the same style as those familiar to readers of *Astronomy and Astro-Physics.* The various tables, notes, &c., which complete this journal of forty-eight pages, form a useful and important addition.

THE AUGUST METEORS.—The prevalence of fine weather during the month of August afforded many observers excellent opportunities of observing the Perseids, and it is not surprising to hear that so many observations were made. *Astronomische Nachrichten* (No. 3192) gives some of the results, showing that at Warendorf, August 8–11, 410 paths were recorded, at Eversunital 72, Brilon 184, Arnsberg 114, Altona Hamburg more than 400, and so on. Prof. Denza, in the current number of *L'Astronomie* (No. 10, October), gives a list of some of the observations made in Italy. He refers to the shower as among "les plus éclantantes remarquées jusqu' à présent," and suggests that for the next few years it should receive special attention. The radiant point he locates as $\alpha = 44°$, $\delta = +55°$, the number of meteors attaining their maximum on the night of the 10th to 11th. Mr. Denning has also a few words to say (the *Observatory* for October) with regard to this shower, commencing first with the inaccuracy shown in observing the Lyrids of April, and pointing out "the same extraordinary differences" manifested in these Perseid observations. The accurate places, as he believes, were obtained by Mr. Booth on August 9, 43° and + 57°, and by Mr. Evershed on August 10, 44° + 57°. On August 16 he himself deduced the radiant as 52° and + 57°, a value agreeing approximately with Kleiher's theoretical position for that date, namely 54° + 59°.

ASTRONOMY OF THE FELLAHIN OF PALESTINE.—An interesting paper by Mr. P. J. Baldensperger, on the beliefs of the Fellahin of Palestine, is found in the] October report of the Palestine Exploration Fund. It appears that the Fellahin know the Pleiades by the name of Thureiyah. Besides this, many of the conspicuous stars and constellations have received names. The following are examples, though the list can be considerably extended :—

Banat Na'asch	The Great Bear.
Nijmetain el-Joz	Castor and Pollux.
Thureiyah	Pleiades.
Hareef el Thureiyah	Auriga.
Sawak el Thureiyah	Aldebaran.
Il Jiddi	Vega.
Nijmet el Danab	Denebola.
Ilsamak	Fomalhaut.
Ilmizâne	Orion's Belt.
Nashallat il mizâne	Betelgeuse and Rigel.
Sawak il mizâne	Sirius.
S'héle	Canopus.
Tareek i-tubânet	The Milky Way.

The planet Jupiter is known as Nijmet el Gharara, Venus as Morning Star, and Mars as Nijmet el Sha'ate. A number of curious stories and beliefs are connected by the Fellahin with the stars, and a few with planets.

GEOGRAPHICAL NOTES.

M. A. HAUTREUX has been engaged this summer (*Bulletin* of the Bordeaux Society of Commercial Geography, 1893, No. 14) in investigating the difficult question of the currents of the Bay of Biscay, by means of specially contrived floats consisting of two bottles attached by a cord a metre in length. The lower bottle being weighted with water keeps the upper one, containing air, from being driven by the wind, and the whole drifts along with the superficial layer of water. The results obtained seem to point to the absence of any current northward along the coast of the bay. From all points of the line at which floats were discharged west of France they showed a tendency to drift rapidly south-eastward towards the south-eastern angle of the bay. The observations will be continued, and the result will be of value in furnishing additional information to sailors of the landward drift that has so often proved fatal to vessels on the north coast of Spain.

THE Queensland Branch of the Royal Geographical Society of Australasia has adopted a resolution approving of Sir Thomas McIlwraith's proposal to adopt an hour-zone system of time reckoning for Australia and New Zealand, with the 150th meridian (ten hours from Greenwich) as a unit, and urging the other branches of the society to take the matter up. The meridian of 150° E. runs through Cape Howe in the south-east of Australia and through the south-east of New Guinea, and its time would hold for the capitals of the three eastern colonies and Tasmania. The next hour interval westward (135° E.) would include the whole of South Australia, and the third (120° E.) would hold good for Western Australia. Eastward the time of the 165th meridian would apply to the south island of New Zealand, and that of the 180th meridian (twelve hours from Greenwich) to the north island and to Fiji.

Globus announces that an exploring and surveying expedition, to which five Germans are attached, has been organised in Brazil to study the less known parts of the Amazon basin and collect information as to ethnography and natural history. The expedition was intended to leave Santos in August, and cross the plateau of Matto-Grosso towards the upper waters of the Amazon, where surveys and scientific collections will be made.

THE last number of the *Mouvement Geographique* gives a sketch-map of Lake Leopold II., which lies south of the Congo. It has been resurveyed, in April 1892, by Mr. Mohun, the United States Consul to the Congo State, who was accompanied by M. De Meuse. The lake extends from 1°5′ S. to 2°45′ S., and its outflow drains into the Congo from the southern end. The lake receives no important streams, but is fed by drainage from extensive marshes which stretch away from its north-western end. The water is shallow, but rises 1·5 metres in the rainy season, inundating a large area of country. The deeply-indented bays serve as harbours for the canoes of the warlike slave-hunting races who inhabit the surrounding country, their villages being hidden deep in the forests at some distance from the shores of the lake.

THE new session of the Royal Geographical Society will be opened by an address on "Geographical Desiderata" by the new President, Mr. Clements R. Markham, F.R.S., on November 13. At the second meeting a paper on the Antarctic regions is expected from Dr. John Murray, of the *Challenger*, which will be followed by a discussion. Other papers which are being arranged for will be announced later. Mr. Mackinder will give the second course of his educational lectures on the relations of geography to history after Christmas, and a course of educational lectures on the principles of commercial geography is now being given, under the auspices of the Society, by Dr. H. R. Mill, in the London Institution.

THE HARVEIAN ORATION.[1]

IT is now 237 years since the illustrious Fellow of this College whose name we are met to commemorate, provided, when two years before his death he conveyed his estate at Burmarsh to the College, that :—

"There shall be once every year a general feast for all the Fellows; and on the day when such feast shall be kept, some one person of the said College shall be from time to time appointed by the President and two Eldest Censors and two Eldest Elects for the time being of the said College (so that the person so to be appointed be not in that behalf appointed two years together), who shall make an Oration publicly, in the said College, wherein shall be a commemoration of all the benefactors of the said College by name, and what in particular they have done for the benefit of the said College, with an exhortation to others to imitate those benefactors, and to contribute their en-

[1] Delivered by Dr. P. H. Pye-Smith, F.R.S., at the Royal College o Physicians, on Wednesday, October 18th.

deavours for the advancement of the Society, according to the example of those benefactors; and with an exhortation to the Fellows and members of the said College to search and study out the Secrets of Nature by way of experiment; and also for the honour of the profession to continue in mutual love and affection among themselves, without which neither the dignity of the College can be preserved, nor yet particular men receive that benefit by their admission into the College which they might expect; ever remembering that '*concordia res parvæ crescunt, discordia magnæ dilabuntur.*'"

I. Concerning the originality of that immortal discovery, which places Harvey in the limited class represented by Aristotle and Archimedes, Copernicus, Newton, and Darwin, it is sufficient to bear in mind the following considerations:—

1st. If Harvey's doctrine of the circulation was not new, why was it opposed by men in the position of Riolanus and Hoffmann, and welcomed as a discovery by Bartolinus and Schlegel and Descartes? Surely his contemporaries were better judges of the novelty of his views than we are!

2nd. Admitting that Servetus and Columbus taught the doctrine of the lesser circulation, we need but a moment's thought to convince us that no complete knowledge of this part of the subject was possible until the existence of a systemic circulation was established; for the one is physically impossible without the other.

3rd. The title of Harvey's great work is not, as it is sometimes quoted, "The Circulation of the Blood," but "*De Motu Cordis et Sanguinis.*" He first showed that the flesh, or parenchyma, of the heart is true muscle, that the heart is not a passive chamber receiving the blood, but a contractile organ expelling it. Until the motive power of the heart was understood there *could* be no true theory of the circulation.

The fact is, that when we know the true solution of a problem, it is easy to see or think we see it in any discussion which preceded the discovery; for there is only a limited number of answers to most questions, and therefore true as well as false solutions are almost sure to have been proposed.

In the writings of Columbus, Servetus, and Cæsalpinus, phrases occur which sometimes seem as if the writers were going to state the truth that Harvey first asserted.

But it would be as reasonable to infer, from such passages, that the circulation of the blood was then known, as from the lines that Shakespeare puts into the mouth of Brutus:

"As dear to me as are the ruddy drops
That visit my sad heart."

As Paley well said, *he* only *discovers* who *proves.* To hit upon a true conjecture here and there amid a crowd of untrue, and leave it again without appreciation of its importance, is the sign, not of intelligence, but of frivolity. We are told that of the seven wise men of Greece, one (I believe it was Thales) taught that the sun did not go round the earth, but the earth round the sun, and hence it has been said that Thales anticipated Copernicus—a flagrant example of the fallacy in question. A crowd of idle philosophers talking all day long about all things in heaven and earth, must sometimes have hit on a true opinion, if only by accident, but Thales, or whoever broached the heliocentric dogma, had no reason for his belief, and showed himself not more but less reasonable than his companions. The crude theories and gross absurdities of phrenology are not in the least justified, or even excused, by our present knowledge of cerebral localisation; nor do the baseless speculations of Lamarck and Erasmus Darwin entitle them to be regarded as the forerunners of Erasmus Darwin's illustrious grandson. Cuvier was perfectly right in his controversy with Geoffroy St. Hilaire; the weight of evidence was undoubtedly on his side. Up to 1859 impartial and competent men were bound to disbelieve in evolution; after that date, or at least so soon as the facts and arguments of Darwin and Wallace had been published, they were equally bound to believe in it. He discovers who proves, and by this test Harvey is the sole and absolute discoverer of the movements of the heart and of the blood.

Concerning the *methods* used by Harvey they were various, and his discovery, like most great advances in knowledge, was not achieved by one of the happy accidents which figure in story books, or by the single crucial, and never-in-after-ages-except-under-license-and-special-certificate-to-be-repeated, experiment which some members of a certain Royal Commission supposed to be the only kind of experiment needed in scientific inquiries.

A perusal of Harvey's own statements makes it plain, it seems to me, that having gained his knowledge of the anatomy of the heart and of the current hypotheses of its function from his Italian masters, he reasoned thus:—First, that the cardiac valves must be intended for such physiological service as their construction would indicate. He believed that every part of this human microcosm has a meaning; that it is by no chance result of blind forces that an organ is adapted to its end. This great postulate is necessary for scientific progress. If the difficulties of physiology, whether normal or morbid, seem so intricate and insuperable that we are tempted to doubt whether the riddle after all has an answer, we must again and again fall back on the faith of Harvey and of Newton, of Boyle and of Linnæus. The great doctrine of natural selection has thrown wonderful light upon the methods by which the results that we see have been reached, but has not impaired the excellence of those results nor their evidence of beneficent design.

Belief then that the body and all its parts is a machine constructed for certain uses, that everything in Nature has a reason and an end—this was Harvey's postulate when he argued out the functions of the heart and vessels from their anatomical construction.

Harvey's second method was that of actual experiment. On this point he leaves us in no doubt. His second chapter is headed, "*Ex vivorum dissectione qualis sit cordis motus,*" and in the introductory chapter which precedes this, he says:—

"Tandem majori indies et disquisitione et diligentia usus, multa frequenter et varia animalia viva introspiciendo, multis observationibus collatis et rem attigisse et ex hoc labyrintho me extricatum evasisse, simulque motum et usum cordis et arteriarum quæ desiderabam comperta habuere me existimabam."

Many of his vivisections were not strictly speaking experiments, but observations—inspection of the living heart and arteries—others were experiments in the modern and restricted use of the word. These were Harvey's methods, as they must be the methods of all natural science. First, observation; next, reflection; then experiment. "Don't think; try," was Hunter's advice to Jenner; an advice that is often needed by an acute inquiring genius like his; still more often by sheer idleness, that will never bring its fancies to the test of fact.[1]

Experiments without hypotheses are often fruitless, but hypotheses which are never brought to the test of experiment are positively mischievous.

How far have the Fellows of this College obeyed Harvey's precept and followed his example in "searching out the secrets of nature by way of experiment." We must, I fear, confess that after the brilliant period of the seventeenth century (in some respects the greatest of our history and certainly the most fruitful in great men) experimental science made slow and uncertain progress, so that between Harvey and Newton, Hook and Grew, Mayow and Boyle on the one hand, and Cavendish, Black and Priestley, Hunter and Hewson on the other, there was a long period of stagnation or even retrogression. Hypotheses and dogmas, misapplied mathematics, imperfect chemistry, and an affected literary style (made more conventional by the practice of writing in a foreign language better fitted for rhetoric than science) contributed to make the eighteenth century comparatively barren, in so far as science generally, and physiology and medicine in particular, are concerned.

The "way of experiment," in the strict sense of the word, has been hitherto most successfully applied to normal physiology. The successors of Harvey were not Sydenham, Radcliffe, Arbuthnot, Garth, Meade, Freind and Heberden, but Lower, Mayow, Hales, Vierordt, Ludwig and Chauveau. *Pathology* as an experimental science is still in its infancy, but the infancy is that of Hercules, and bids fair to strangle such dire pests as anthrax, cholera, tetanus and hydrophobia.

Before quitting this part of my subject, I would fain correct a popular misconception that Harvey was a neglected genius—that his contemporaries, his professional brethren, and in particular this ancient College, refused to listen to his new notions, ridiculed his discoveries, and spoiled his practice. Whether as his fame grew his practice diminished, we cannot tell. If so, his patients were the losers. What Harvey and every honest man cares for, is not popular applause, but the confidence and esteem of his comrades; and this he deserved and received. It was as lecturer at this College that he propounded

[1] Ea autem vera esse vel falsa. Sensus nos facere debet certiores, non Ratio; αὐτοψια non mentis agitatio. Second Epistle to Riolanus, p. 133. (College edition).

his discoveries; it was here that he found his disciples and his friends. Here he was urged to take the presidential chair; and here his statue was erected, five years before his death, with the inscription, "*Viro monumentis suis immortali.*" It would have been a poor compliment to his elaborate demonstrations, and unworthy of a liberal profession, if so startling a revolution as Harvey proposed had been accepted without inquiry. It was considered, it was discussed, and, without haste but without timidity, it was at last accepted—the very way in which Darwin's theory was received and criticised, and finally adopted by Lyell and by Hooker. Let then no scientific impostor or medical charlatan quote Harvey to console him under merited censure.

II. Of Harvey's writings, the second, and by far the longer treatise, is that upon Generation. This formed the subject of a valuable criticism in the Harveian Lecture by the late Sir Arthur Farre. It is full of interest and contains many observations that remain true for all times, many acute criticisms, and a few broad and true generalisations, such as the famous dictum—"*Omnia animalia ex ovo progigni.*" Perhaps, however, what most strikes the reader of this treatise is the *learning* of the writer. He is familiar with his Aristotle, and quotes from Fabricius and other writers with much greater freedom than in the succinct and almost sententious treatise, "*De Motu Cordis et Sanguinis.*" Some would have us believe that here, as in other cases, erudition was a clog upon genius. This question has been often discussed, and it has even been maintained that he is most likely to search out "the secrets of Nature by way of experiment" who comes fresh to the task with his faculties unexhausted by prolonged reading, and his judgment uninfluenced by the discoveries of others. This, however, is surely a delusion. Harvey could not have discovered the circulation of the blood had he not been taught all that was previously known of anatomy. True, no progress can be made by mere assimilation of previous knowledge. There must be intelligent curiosity, an observant eye, and intellectual insight.

"Doctrina sed vim promovet insitam,"

and few things are more deplorable than to see talent and industry occupied in fruitless researches, partially rediscovering what is already fully known, or stubbornly toiling along a road which has long ago been known to lead nowhither. We must then instruct our students to the utmost of our power. Whether they will add to knowledge we cannot tell, but at least they shall not hinder its growth by their ignorance. The strong intellect will absorb and digest all that we put before it, and will be the better fitted for independent research. The less powerful will at least be kept from false discoveries, and will form (what genius itself requires) a competent and appreciative audience. Even the dullest scholars will be respectable from their learning, and if they cannot make discoveries themselves, can at least enjoy the delight of intelligently admiring the discoveries of others.

III. There is, however, a third phase of Harvey's intellectual work of which, unfortunately, the records have for the most part perished, and which has not, perhaps, been duly appreciated. What I believe Harvey contributed, or would, but for adverse fate, have contributed to medicine as distinct from physiology, was a systematic study of morbid anatomy. In the following passage he speaks of the great benefit that would ensue from the regular observation of the structural changes produced by disease:—

"Sicut enim sanorum et boni habitûs corporum dissectio plurimum ad philosophiam et rectam physiologiam facit, ita corporum morbosorum et cachecticorum inspectio potissimum ad pathologiam philosophicam."

Now this was a new notion. It was not uncommon for the body to be opened after death, especially in the case of great personages, either for the purpose of embalming or for discovering (as it was supposed) the fact of poison or other foul play; and occasionally a physician would obtain permission for a like inspection when something unusual in the symptoms had excited a laudable curiosity to ascertain their cause. But the records of such inspections in the seventeenth century by Bartolinus, or Tulpius, or Bonetus, or, in our own country, by Mayerne, or Bate, or Morton, are fragmentary, their object being limited to the individual case. There was no attempt to search out the secrets of nature in disease by a systematic observation of the state of the organs after death, nor was there for more than a century after Harvey's death. Morgagni in Italy; the French anatomists of the early part of this century, Corvisart and Laennec, Broussais and Cruveilhier; in Germany Meckel and Rokitansky, and in England Baillie, Abercrombie, Carswell and Bright—these were the founders of scientific pathology on a sure anatomical basis almost within living memory.

Not only had Harvey the prescience to recommend the study of morbid anatomy for itself, but he had himself carried it out by recording a large number of dissections, or, as we should now call them, inspections, of diseased bodies. Unfortunately most of these post-mortem reports, with his observations on the generation of insects, and other manuscripts were destroyed, or irrevocably dispersed, when his house in London was searched while he was with the King at Oxford. If the records of these inspections had been published, may we not asssume that Harvey's great authority would have set the fashion, and that the systematic study of morbid anatomy would have begun a century and a half earlier than it did? And think what this would have meant. With the exception of a few shrewd observations, a few admirable descriptions, and here and there a brilliant discovery, such as the origin and prevention of lead colic and of scurvy and the introduction of vaccination, it may be said that medicine made no important progress between the time of Harvey and that of Laennec. The very notion of diagnosis in our modern sense of the word depends upon morbid anatomy. The older physicians seldom attempted to determine the seat of an ailment. Disease was looked upon not as a condition depending upon disordered physiological functions, but as something external, attacking a previously healthy person, disturbing, and, if not expelled by art, finally destroying him; while any structural changes which were found after death were regarded rather as the effects than the causes of the symptoms during life.

Now, the ambition of every intelligent student—and in medicine we are life-long students—is to fix upon the most objective, certain, and important of the symptoms of a patient, to follow out this clue, to determine the organ affected and the nature of the affection, so that in his mind's eye the tissues become transparent and he sees the narrow orifice for the blood-stream and the labouring muscle behind it; or the constricted loop of intestine with violent peristalsis above and paralysis below, the blood-current stopped and congestion passing hour by hour into gangrene; or, the spinal cord with grey induration of a definite region, and the motors, sensory and trophic changes which physiologically ensue.

Sometimes this minute search to fix upon the locality and exact nature of a lesion has been ridiculed; and we are asked what benefit to the patient such knowledge when attained can bring. We answer, that in medicine, as in every other practical art, progress depends upon knowledge, and knowledge must be pursued for its own sake, without continually looking about for its practical application.

Harvey's great discovery (which we physicians rightly celebrate this day) was a strictly *physiological* discovery, and had little influence upon the healing art until the invention of auscultation. So also Dubois Reymond's investigation of the electrical properties of muscle and nerve was purely scientific, but we use the results thus obtained every day in the diagnosis of disease, in its successful treatment, and in the scarcely less important demonstration of the falsehoods by which the name of electricity is misused for purposes of gain.

It is true that Bernard's discoveries of the diabetic puncture and of the digestive function of the pancreas have not yet received their practical application. He was right when he said, "*Nous venons les mains vides, mais la bouche pleine d'esperances légitimes*"—but he should have spoken for himself alone.

The experiments on blood-pressure begun by Hales, and carried to a successful issue in our own time by Ludwig, have already led to knowledge which we use every day by the bedside, and which only needs the discovery of a better method of measuring blood-pressure during life, to become one of our foremost and most practical aids in treatment.

Again, we can most of us remember using very imperfect physiological knowledge to fix, more or less successfully, the locality of an organic lesion in the brain. I also remember such attempts being described as a mere scientific game, which could only be won after the player was beaten, since when the accuracy of diagnosis was established, its object was already lost; but who would say this now, when purely physiological research and purely diagnostic success have led to one of the most brilliant achievements of practical medicine, the operative treatment of organic diseases of the brain?

It has often been questioned whether the study of morbid anatomy has not withdrawn attention from morbid physiology; and, again, whether the time employed upon pathological researches would not have been better spent in directly therapeutical inquiry. To both these questions I take leave to answer, No. Anatomy must precede physiology, whether in the normal or the diseased state. The humoral physiology of the ancients did infinite mischief (mischief not yet exhausted), because it lacked the sound basis of anatomy; and experimental pathology, necessary and important as it is, and valuable as even its first endeavours have proved, was impossible without previous knowledge of the anatomy and histology of disease. As to therapeutics, I hold that for the successful cure of a patient it is far better that his physician should have a thorough and extensive knowledge of morbid anatomy, than that he should be acquainted with all the baths and waters, the hotels and lodging-houses throughout the world, or familiar with the barbarous names and pretended virtues of all the advertised nostrums that deface the fair English fields from London to Oxford. The public suppose that it is *their* business to know what is the matter, and the doctor's to find the remedy; if so, our art would be confined to learning the name of the patient's disorder by letter, post-card, or telegram, and looking up in an index of remedies the twenty or thirty drugs which are "good" for that particular complaint. *We* know that the real difficulty is to ascertain the nature and origin of our patient's disorder; when that is done, the treatment in most cases is obvious, and in many effectual; when it is not done, our treatment is vacillating, and either futile or mischievous. We have already ample means at our disposal for influencing almost every organ of the body. A new tool is occasionally offered us which deserves proving, but what we want far more is knowledge how to use the tools that we have. Treatment without diagnosis, besides its inefficiency, brings us for the time unpleasantly near to the charlatan who, whatever title he may assume, is always therapeutical and never pathological. Rational, bold, and effectual treatment, whether preventive or curative, must always depend upon accurate diagnosis and sound pathology, and the power of diagnosis depends upon that systematic inspection of the bodies of diseased persons which was recommended and practised by Harvey.

"Ad hanc inspectionem, cum Heraclito apud Aristotelem, in casam furnariam (sic dicam) introire si vultis, accedite: nam neque hic Dii desunt immortales. Maximusque omnipotens Pater in minimis et conspectior vilioribus quandoque est."

Suffer me, then, Mr. President and Fellows of this College, to obey the instructions of the founder of this lecture, by exhorting my hearers, and especially those Fellows who are junior to myself, to emulate, according to the varied talents entrusted to each, the example of Harvey in these three particulars:—

(1) In investigation by experiment, whether by pathology or physiology.

We have now difficulties unknown to Harvey in carrying out this duty, for duty it certainly is, incumbent upon all who have the opportunity and the necessary training. The countless experiments on living animals which were carried out during the 17th century in all civilised countries—in Italy, Holland, Denmark, France, Germany, and England—bore a rich fruit of physiological knowledge. If the anatomy of the human body was thoroughly ascertained by the great men of the 16th century, by Vesalius, Sylvius, and their successors, it is no less true that to the 17th century is due the discovery of the elements of physiology. The action of the heart and the circulation of the blood, the absorption of chyle by the lacteals and thoracic duct, the mechanism of respiration and some knowledge of its chemical effects, the function of secretion by glands, the minute structure of the eye and ear, and of the reproductive apparatus, and a knowledge—imperfect, but true as far as it went—of the functions of the brain and nerves, these were the achievements of the 17th century due to Harvey, Glisson, Willis, and Mayow, among our own countrymen, and to Pecquet, Malpighi, Leuwenhoeck, De Graaf, Swammerdam, Aselli, Redi, and Bartolinus. In all this brilliant advance of knowledge, experiment upon the lower animals was the method used, and the method is as indispensable now.

Anyone conversant with a single branch of natural science is aware that experiment, as well as observation, is necessary. Who would expect discoveries in physics, or in chemistry, without laboratories and experiments? Do not botanists investigate the functions of plants by dissection, by microscopic and chemical investigation, and by *experiment?* Have we not this very year celebrated the important results of fifty years' *experimental* researches into the life and growth of plants by Lawes and Gilbert? And is it not obvious that the same necessary well-tried and indispensable method of inquiry must be continued in the case of animals? Happily the same experimental science has discovered the means of abolishing the tribute of suffering which the brute creation paid in the hands of Harvey and Hales, of Haller, Magendie, and Sir Charles Bell. By means of chloroform and other anæsthetics, and by means of the antiseptic methods which we owe to Sir Joseph Lister, the subjects of experiment are spared the pain and shock of an operation, and the pain which used to follow an operation. In fact, almost the only experiments upon the lower animals which involve distress are those which are most immediately and directly useful to ourselves and to them; inoculations, namely, with a view to reproduce diseases, and the direct therapeutical testing of drugs. Cruelty is utterly repugnant to our calling; and it seems absurd that men, who will with just confidence entrust themselves and the lives of those nearest to them to our protection and care, should yet so far distrust us as to shackle attempts to improve our knowledge and our power by cumbersome and ridiculous restrictions. Let us hope that on the one hand increasing humanity and gentler manners will extend compassion for the lowest of God's creatures from the educated classes of England and America until it permeates all ranks and all nations; and that on the other full liberty will be given to the prosecution of researches, laborious and thankless in themselves, but of the utmost value for the relief and prevention of disease in man and brute alike. May I also express a hope that those who administer our laws will take heart of grace, and in this, as in other matters, try whether Englishmen do not prefer the conscientious maintenance of a statesman's own judgment before a time-serving submission to ignorant clamour.

(2) In the second place, I would exhort my brethren, and especially the members of this College, to cultivate learning. Harvey went to study in Italy, then the nursery of science as well as of art, and he was familiar with the writings of Plato and Aristotle and Virgil, as well as with those of his immediate predecessors, Fabricius and Columbus. So in that golden time which comes to most of us, between taking the academical degree and becoming immersed in the daily duties of hospital life, I strongly advise a visit to one of the German universities, or to Paris, to acquire the key to the two languages in which the best modern books are written; and to widen the mind by seeing the aspect of science and affairs from a continental standpoint. It is lamentable that there is so little professional intercourse between the students of one of our London schools and the teachers of another. The laudable energy which has made each of them complete, and well-equipped colleges has had this drawback, that at the present day the attention of a diligent student is more confined to the teaching and practice of his own school than it was sixty or seventy years ago.[1] The narrowness and prejudice bred by this isolation may be corrected by a visit to the famous sister universities of Edinburgh or Dublin; for their complete removal no prescription is so efficient as a prolonged stay in continental laboratories and hospitals. But even such a broad and liberal education, even familiarity with the daily advances of medical science recorded in periodicals and archives and year-books, or transmitted by telegraph to the wondering readers of the daily newspapers, is not all that is needful to make a learned physician. We know well the difference between reading of an experiment, or even seeing it performed, and doing it with our own hands. We know the difference between studying a pathological atlas, or even a cabinet of histological slides, and seeing and handling morbid tissues and making sections for oneself. So also is there all the difference between learning the present conclusions as they stand recorded in the

[1] Let us hope that the University of London when reconstituted by the labours of the Royal Commission, which is now preparing its report to the Crown, may provide by the regulations of its medical faculty for more community of teaching and learning among students of medicine in this city.

last edition of a text-book or compendium and tracing the steps by which our present knowledge has been reached.

With regard, for instance, to the physiology of the circulation, it is not only curious but instructive to follow its gradual growth from Galen and Vesalius, Columbus, Cæsalpinus, and Servetus, to Harvey and Lower and Malpighi, to Hales and Vierordt, to Ludwig, and Chauveau, and Gaskell, and Roy. The only true scientific method is the historical one. If we only know the results of a science without the steps by which they have been reached, we have indeed its practical use, but lose half its educational value. We are almost in the position of an engineer who knows the conclusions of trigonometry by rote, but is ignorant of the demonstration. I would therefore urge upon junior Fellows, while still enjoying the prospect rather than the fruition of professional success, to spare some of the time which is unoccupied by work in wards and laboratories for the perusal of such antiquated works as have been published as much as twenty years ago, and particularly for gaining acquaintance at first hand with classics like Virchow's "Cellular Pathology," and the lectures of Watson, Trousseau, and Stokes; or, if their time and inclination does not allow of more extended researches, at least to read such succinct masterpieces as Laennec's "Mediate Auscultation," Heberden's "Commentaries," Sydenham's "Treatise on Gout," and Harvey "On the Movement of the Heart and of the Blood."

(3) I would, moreover, exhort Fellows of the College to see that, while all the new methods of experimental pathology and pharmacology are carried out by duly trained physiologists, we do not neglect the fundamental method taught and practised by Harvey of inspecting the bodies of those who have died of disease. It was this union of morbid anatomy with clinical observation which made the discoveries of Laennec and of Bright really fruitful. Without these autopsies, clinical medicine is but an empirical art, diagnosis a sham, and treatment little better than quackery. Exclusive attention to therapeutics is apt to bring a man dangerously near to homœopathy and other pretended systems of treatment, but sound pathology, and diagnosis controlled by *post-mortem* inspection, give positive knowledge and that union of modest self-confidence and prudent enterprise which become the physician.

Lastly, I have to fulfil the duty of exhorting the Fellows of this ancient College "to continue in mutual love and affection" among ourselves; and this is the easiest task of all. For, if we must admit that experimental science in England, and particularly scientific pathology, is not surpassing our byegone achievements as it ought to surpass them, considering the increased number of competent labourers and the vastly improved methods of research; and if we admit that the crowd of modern literature, and the distractions which we fondly imagine to be peculiar to our generation, leave small opportunity for the cultivation of ancient learning; and if the prejudices of our patients, both gentle and simple, still make post-mortem inspections less common and systematic than they should be—whatever, I say, may be our shortcomings in these or in other respects—your Harveian orator may most honestly congratulate the College and the profession upon the concord and mutual esteem which has happily marked our history from the days of Linacre to those of Harvey, from the days of Arbuthnot and Garth to those of Meade and Freind, from the days of Fothergill and Heberden to those of Matthew Baillie, of Babington, and of Sir Thomas Watson. Long may this continue, for thereon depend not only the dignity and peace of our profession, but in great measure our power of doing good. However ignorantly our patients will sometimes decry what they call professional etiquette, the wiser among them know (and in the long run the wise lead the foolish) that this term really means the observance of the rules which distinguish a profession from a trade, which make our calling honourable as well as honest, which check the arts of advertisement and direct our ambition to obtaining the suffrages, not of the public which *cannot*, but of our profession which *can*, judge truly—rules of conduct which are, in fact, nothing but the carrying into daily practice of the golden rule to do to others as we would they should do to us. For maintaining and strengthening this spirit of concord and good feeling, we depend upon each one of our Fellows, but especially on the example and authority of our Head—an example and authority which, as the College well knows, are worthily maintained by the untiring devotion to its best interests of our honoured President.

THE EFFECT OF WATER VAPOUR ON ELECTRICAL DISCHARGES.

A VERY interesting paper by Prof. J. J. Thomson, on the effects of electrification and chemical action on a steam jet, and of water vapour on the discharge of electricity through gases, appears in the October number of the *Philosophical Magazine*. In it the author first considers the effect of an electrical field on the surface tension of a water drop, and he shows that if the electrical field is uniform, the diminution in the surface tension is very small and independent of the size of the drop; so that a uniform field will not be able to counterbalance the effect of surface tension, since the latter varies inversely as the radius of the drop, and therefore when the drop is excessively small must be greater than the constant effect due to the electric field. When, however, the electric field instead of being uniform is due to a number of charged atoms distributed throughout the volume occupied by the steam, the effect of the electric field in diminishing the surface tension varies inversely as the square of the radius of the drop. Thus for very small drops the electrification will overpower the cause (surface tension) which, under ordinary circumstances, puts an end to the existence of small drops. The above seems capable of explaining the effects of electrification on a steam jet first observed by Helmholtz, for the electricity which escapes into the gas is carried by charged atoms of the gas, and since in the region immediately around these atoms there will be a very intense electric field there will be a tendency for the steam to condense into drops in these regions. Helmholtz also discovered that chemical action in the neighbourhood of the jet affected it in much the same way as a discharge of electricity. If the forces which hold the atoms together in a molecule are electrical in their origin, so that in a diatomic molecule one atom has a positive and the other an equal negative charge, the above explanation will also apply to this case. For when the molecule of the gas is in the ordinary state, the equal and opposite charges of the atoms will, in the region outside the molecule, neutralise each other's effect, so that the electrical field round a molecule will be much less intense than that round a single charged atom, and thus, though the field round the latter may be sufficient to cause condensation, that round the molecule may not. When, however, the molecules which enter into chemical combination come together and form a new compound, requiring a rearrangement of the atoms, then while the chemical change is going on, there will be an interval during which the atoms are comparatively free, and there will be an electric field almost as strong as if the atom were dissociated.

The author also considers the effect of moisture in promoting chemical action, for if the forces which hold the atoms in the molecule together are electrical in their origin it is evident that these forces will be very much diminished when the molecule is near the surface of, or surrounded by, a conductor or a substance like water having a high specific inductive capacity. Thus if A and B represent two atoms in a molecule placed near a conducting sphere, then the effect of the electricity induced on the sphere by A will be represented by an opposite charge placed at the image of A in the sphere. If A is very near the sphere, this opposite charge will be very nearly equal to that at A. Thus the effect of the sphere will be to practically neutralise the electrical effects of A, and as one of these effects is to hold the atom B in combination, the affinity between the atoms A and B will be almost entirely annulled by the presence of the sphere. Molecules condensed on the surface of a drop of water or surrounded by water will thus be practically dissociated, or at any rate the forces between their component atoms will be much reduced. Since water vapour produces so great an effect on chemical combination, it is interesting to investigate whether its presence has any considerable influence on the passage of electricity through gases, since there is strong evidence that this phenomenon is closely connected with chemical changes taking place in the gas through which the discharge takes place. Observations were made on dry and damp hydrogen, and show that there is a marked difference both in the appearance of the spark and in the proportion between the potential difference necessary to produce the first spark through the gas, and that which is sufficient to cause one to follow it immediately afterwards. In the damp gas this difference was comparatively small, averaging about ten per cent. In the dry gas, however, this effect attains quite abnormal proportions, the potential difference required to produce the first spark being often more than twice that required to maintain it when once started. These experiments show that the behaviour of a gas with reference to the passage of an electric spark is analogous to that of a vapour condensing to a liquid, the freezing of a liquid, or the deposition of crystals from a saturated solution. For in the case of a gas which contains a foreign substance (water vapour) the potential difference which the gas can support without a spark passing is approximately steady, but when the gas is carefully dried it can support an abnormally large potential difference, though when once the discharge has started the potential difference at once falls to its normal value. The passage of the spark producing a supply of modified gas which persists for some time after the discharge has stopped.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—The opening of the new department of Human Anatomy was the occasion of some ceremony on Saturday afternoon. The Vice-Chancellor presided at a large gathering of scientific and medical men, including some distinguished visitors from the leading medical schools and universities. After speeches from Sir William Turner, Mr. Arthur Thomson, Sir Henry Acland, and Prof. MacAlister, the Vice-Chancellor declared the buildings open, and the proceedings closed with a vote of thanks to the Vice-Chancellor, moved by Prof. Burdon Sanderson.

The lectures and practical courses in the Natural Science Department are as follows for the current term:—In Physics, Prof. Clifton lectures on Electricity, and gives practical instruction with the assistance of Mr. J. Walker and Mr. S. A. F. White. Mr. R. E. Baynes, lectures at Christ Church on Heat and Light, and Sir John Conroy and Mr. F. J. Smith lecture at Balliol and at Trinity College, respectively, on Elementary Physics and on Mechanics and Physics.

In Chemistry, Prof. Odling lectures on Organic Chemistry, and Mr. W. W. Fisher, on Inorganic Chemistry. Other lectures and practical instruction are given by Mr. J. Watts, Mr. V. H. Veley, Mr. J. E. Marsh, and Mr. J. A. Gardner. Mr. Vernon Harcourt and Mr. P. Elford lecture at Christ Church and St. John's respectively. Prof. A. H. Green lectures on Geology in the Museum on Mondays, Wednesdays, and Fridays.

Prof. Ray Lankester lectures three days a week on the Comparative Anatomy of the Vertebrata, and Dr. W. B. Benham and Mr. G. C. Bourne give other lectures in the Linacre Professor's Department. Mr. J. Barclay Thompson lectures on the Osteology of Fish and Amphibia; and the Hope Professor of Zoology, on Means of Defence in the Struggle for Existence.

In Physiology, lectures and practical instruction in the subjects for the Final Honour Examination are given by Prof. Burdon Sanderson, Mr. J. S. Haldane, and Mr. M. S. Pembrey.

Prof. S. H. Vines gives advanced and elementary courses on Botany at the Botanical Gardens.

In Anthropology, lectures are announced by Dr. E. B. Tylor, by Mr. H. Balfour, and by Mr. Arthur Thomson.

It is announced that the examination for a Biological Fellowship at Merton College will commence on November 14.

Examinations for Natural Science Scholarships and Exhibitions at Balliol, Christ Church, and Trinity, are announced to begin on November 21.

Cambridge.—The Vice-Chancellor gives notice that Mr. H. Yule Oldham, University Lecturer in Geography, will deliver an inaugural lecture on the progress of geographical discovery, in the large lecture theatre of the chemical laboratory, on Tuesday, October 24, at noon.

During the Michaelmas and Lent terms, Mr. Oldham will give courses of lectures on the principles of physical geography, in the same theatre, on Thursdays, at noon, beginning on October 26.

The Council of the Royal Geographical Society offer to award during the present academical year an exhibition of £100 to be spent in geographical investigation (physical or historical) of some district approved by the Council, to a member of the University of not more than eight years' standing, who shall have during his residence attended the courses of the lectures in geography. Further particulars will be announced.

The office of Director of the Fitzwilliam Museum is vacant by the resignation of Dr. Middleton. A new Director will be appointed on Friday, November 17. The stipend is £300 a year. Candidates are to send their names to the Vice-Chancellor by Friday, November 10.

The Walsingham Medal, founded by the High Steward of the University, will be offered during the present academical year for the best monograph or essay giving evidence of original research in any subject connected with biology or geology. Essays are to be sent to Prof. Newton by October 1, 1894.

There are this year 132 freshmen who have indicated their intention of studying medicine in the University.

Entrance Scholarships in Natural Science have been awarded at Christ's College to A.V. Cunnington (£60), Clifton College, and J. Hart-Smith (£30), Berkhampstead School; and at Emmanuel College to W. F. A. Ermen (£50), Clifton College, and R. G. K. Lempfert (£50), Manchester Grammar School. At Downing College an Examination for Minor Scholarships (£50) in Natural Science will be held on April 17, 1894. At St. John's the Examination for Natural Science Scholarships (£80 and under) and Exhibitions (£50 and under) will begin on December 5, 1893.

The United States Bureau of Education has published a remarkable "Circular of Information," by Dr. Arthur Macdonald, entitled "Abnormal Man." The volume includes essays on education and crime and related subjects, with digests of literature and an extensive bibliography. With regard to the effect of education on crime a statistical investigation shows that in France and Italy there has been an increase of both education and crime. Germany shows an increase of habitual criminality and a general increase of both university education and crime. As far as statistics are accessible, Austria shows an increase in education and a decrease in crime. Also, while there has been a decrease in the number of convictions for crime from 1881 to 1887 in Norway and Sweden, there has been an increase in education. But in Norway alone for the year 1888–89 there was an increase in the number of crimes. In England, Scotland, and Ireland all statistics are in accord in showing an increase in education and a decrease in crime from 1885–1890. Japan and Saxony also exhibit an increase in education and a decrease in the number of convictions. It thus appears that while some countries show an increase in both education and crime, yet not a few, and some of the most developed nations, show an increase of education and a decrease of crime. The statistics, therefore, fail to show the exact relation between education and crime.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xv. No. 3. (Baltimore, 1893).—On groups whose orders are products of three prime factors, by F. N. Cole and J. W. Glover (pp. 191–220). In this paper the authors fully determine the groups for three prime factors, equal or unequal. Those of order pq and p^2 are known from Netto.—The nature and effect of singularities of plane algebraic curves, by Miss Scott (pp. 221–243) is a continuation of the paper in vol. xiv. In the earlier memoir the method employed was stated to be directly applicable, in general, to the determination only of the joint components of the singularity; in this the restriction is removed, and it is shown that the process enables one, in every case, to enumerate the double lines (double tangents and inflexional tangents) involved in the singularity. —The elliptic irregularities in the lunar theory, by E. W. Brown (pp. 244–263), gives a general solution in series of the problem: a system of three bodies is in motion in one plane, the first is revolving about the second, and is disturbed from its elliptic orbit by the third. The third body is supposed to be of infinite mass, and to be moving in a circle of infinite radius with a finite angular velocity. Given the relative positions of the three bodies at any one time, to find their relative positions at any other time. The differential equations used at the outset are given in Dr. Hill's paper (vol. i.) and M. Poincaré's researches (*Acta Math.* vol. xiii.) afford considerable help in the work.—On the transformation of linear differential equations of the second order with linear coefficients, by Oskar Bolza (pp.

264–273), is a fresh treatment of the problem by methods of the theory of invariants.—On certain properties of symmetric, skew-symmetric, and orthogonal matrices, by W. H. Metzler (pp. 274–282) proves in another way properties of these matrices which have been obtained by Dr. Taber (*L. Math. S. Proc.* vol. xxii.), and Mr. Buchheim (*Messr. of Math.* vol. xiv.). The number closes with a deduction and demonstration of Taylor's formula, by W. H. Echols (pp. 283–4).

Symons's Monthly Meteorological Magazine for September contains an interesting climatological table for seventeen selected stations in the British Empire, for the year 1892. This valuable summary has now been published for several years, and corresponding monthly tables with remarks have been also regularly printed since July, 1881. The highest temperature in the shade was 110°·8 at Adelaide on January 20. This station also recorded the highest temperature in the sun, and had the lowest mean humidity. The lowest shade temperature was -44°·4 at Winnipeg, on January 18; this station had also the greatest yearly and daily range, and the lowest mean temperature. The dampest and most cloudy station was Esquimalt. The greatest rainfall was 95·1 inches at Bombay, and the least, 21·3 inches at Jamaica. Attention is again drawn to the fact that the Australian stations record higher temperatures both in shade and in sun than occur at the East Indian stations. A table is given of the absolute maximum temperature in shade and sun for each of the ten years 1883–92, at Adelaide and Calcutta, and shows an average excess at Adelaide of 5°·2 in shade, and 6°·4 in sun; but the heat is more prolonged in India, and in the hottest months the average maxima in the shade are always higher at Calcutta.

Wiedemann's Annalen der Physik und Chemie, No. 9.—Luminous phenomena in vessels filled with rarefied gas under the influence of rapidly alternating electric fields, by H. Ebert and E. Wiedemann. Gas vessels without electrodes were placed between the condenser plates of a Lecher wire combination. The luminous phenomena were investigated and discussed from the point of view of tubes of electric force undergoing displacement. It was shown that the portion of energy dissipated by radiation is perfectly commensurable with that occurring in the field generally. The glowing of a gas is therefore a sufficient cause for diminution of pressure in tubes of force, and hence for the displacement of tubes in the field, leading to a dissipation of the energy contained in them. Experiments were also made with tubes fitted with electrodes, one or both of which were attached to an end of the Lecher system. It was shown that any metal plate in contact with a rarefied gas and exposed to slightly damped electric oscillations, shows all the phenomena of a kathode. Also, that at every wall suitably crossing a gaseous space filled with electric oscillations a kathode is produced.—Vapour pressures of aqueous solutions at 0° C. by C. Dieterici.—Thermo-electric studies, by E. Englisch.—Concerning the physical interpretation of thermo-electricity, by F. Braun.—Density of dilute aqueous solutions, by F. Kohlrausch and W. Hallwachs.—Solubility of some "insoluble" bodies in water, determined by the electric conductivity of the solutions, by F. Kohlrausch and F. Rose. The determination of small quantities of "insoluble" substances in a large amount of water is subject to many experimental errors due to the necessity of evaporating large quantities of water at the boiling point, whereby the solubility of the material of the dish becomes a disturbing factor. As the laws governing the relation between concentration and electric conductivity are fairly well known, it is possible to arrive at an estimate of minute quantities of dissolved matter by a determination of the electric conductivity of the solution. This method has proved to be very simple, expeditious, and accurate.—On heat generated by dielectric polarisation, by A. Kleiner.—Experiments on the generation of electricity by small drops, by A. L. Holz. A jet of mercury was projected upon an amalgamated copper plate, whence it rebounded in small globules on to a glass plate, and thence to the electrometer. The increase of potential was found to be proportional to the sectional area of the jet, the pressure and height of fall of the mercury, and the size of the saturated glass plate.—Dielectric constants of liquid bodies as dependent upon temperature and the Mossotti-Clausius formula, by A. Franke.—Experiments on the interference of electric waves in air, by I. Klemencic and P. Czermak.—Notice on secondary heatings of galvanic cells, by H. Jahn.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 4.—Henry John Elwes, President, in the chair.—Mr. F. Merrifield exhibited specimens showing the effects of temperature in the pupal stage on several species of Lepidoptera. *Vanessa polychloros* was much darkened, especially towards the hinder margin, by a low temperature. *Vanessa c-album* showed effects on both sides, especially in the female; they were striking on the under side. Some *Vanessa io* showed the gradual disintegration, by exposure to a low temperature, of the ocellus on the fore wing, which in the extreme specimens ceased to be an ocellus, and was a remarkable confirmation of Dr. Dixey's views of the origin of that ocellus, as exemplified in the plate attached to his paper in the Entomological Society's Transactions for 1890. Mr. Goss stated that in his experience of *V. c-album* in Northamptonshire, Gloucestershire, Herefordshire, and Monmouthshire, the form with the pale under side was the first brood, occurring in June and July; and that the specimens of the second brood, occurring from the end of July to October, were invariably dark on the under side.—Mr. A. H. Jones exhibited Lepidoptera collected in Corsica in June last, including dark forms of *Polyommatus phlæas*, *Lycæna astrarche*, in which the orange marginal band is very brilliant on upper and under sides of both wings, *Lycæna argus*, the females of which are much suffused with blue, probably var. *calliopis*: a series of *Vanessa urticæ* var. *ichnusa*, bred from larvæ, *Argynnis elisa*, *Satyrus semele* var. *aristæus*, *Satyrus neomiris*, *Cœnonympha corrina*, both spring and summer brood, and many others.—Mr. G. C. Champion exhibited for Mr. G. A. J. Rothney, a number of *Methoca ichneumonoides*, Latr. (female), taken at Bexhill, Sussex, showing great variation from the usual large black and red form.—Dr. D. Sharp, F.R.S., exhibited a pupa of *Galleria melonella*, on which the eggs of a parasitic Hymenopteron had been deposited while the insect was in the cocoon. He also exhibited the hitherto unique *Asprostoma planifrons*, Westw.—Mr. J. J. Walker exhibited specimens of the following species, viz. *Halobates sericeus*, from the Pacific; *H. sobrinus*, and *H. wüllerstorffi*, from Marquesas Islands; *H. princeps*, from the China Sea; and a female of *H. wüllerstorffi*, with ova attached.—Mr. W. H. B. Fletcher showed a variable series of 75 specimens of *Cymatophora or*, bred in 1893 from larvæ from Sutherland, a series of about 40 *C. ocularis* bred-in from stock from Oundle; also a series of 33 moths, all females, supposed to be hybrids between *C. ocularis* male and *C. or* female, from the above stock in each case, bred as a second brood in August and September, 1893. He stated that he placed the reputed parents in a muslin sleeve on a branch of *Populus nigra*, and did not open the sleeve until the resulting larvæ required fresh food. The supposed hybrids resembled the female parent, except that both orbicular and reniform stigmata were very conspicuous, being pure white filled up slightly with black.—Mr. F. J. Hanbury exhibited a specimen of *Leucania vitellina*, taken at Brockenhurst on August 24, 1893, and another taken at Freshwater, Isle of Wight, on September 7; also an extraordinary *Gonepteryx rhamni*, showing red blotches at the tips of the fore wings, taken at Walthamstow, Essex.—Mr. C. G. Barrett exhibited a gynandrous *Argynnis paphia* recently taken in the New Forest by Mr. Cardew.—Mr. J. M. Adye exhibited a specimen of *Deilephila livornica* recently caught at Christchurch, Hants.—Mr. Elwes exhibited and described two species of the genus *Œneis* (*Chionobas*, Bdv.) *Œ. beani* and *Œ. alberta*, from North America, which had not been previously described, and stated that he had prepared a revision of this very difficult genus, which would be read at the November meeting.—Mr. Osbert Salvin, F.R.S., exhibited a new genus and species of Papilionidæ (*Baronia brevicornis*). He also communicated a paper entitled "Description of a new genus and species of Papilionidæ from Mexico."—Dr. Sharp read a paper entitled "On the Cost and Value of Insect Collections." Mr. W. F. H. Blandford, Mr. McLachlan, F.R.S., Mr. Jacoby, Mr. Waterhouse, and the President took part in the discussion which ensued.—Prof. Auguste Forel communicated a paper entitled "Formicides de St. Vincent, récoltées par Mons. H. H. Smith."—Mr. Blandford read a paper entitled "Description of a New Subfamily of the Scolytidæ." The President, Mr. Jacoby, and Mr. Waterhouse took part in the discussion which ensued.

PARIS.

Academy of Sciences, October 9.—M. Lœwy in the chair.—On the theory of pyro-electricity and piezo-electricity, by Lord Kelvin.—On a class of new transcendentals, by M. Emile Picard.—Theorem on triple orthogonal systems, by M. Lucien Lévy.—Circles or spheres derived from a plane or solid envelope of any class, by M. Paul Serret.—On the aperture fringes, in the experiment with parallel gratings, by M. Georges Meslin. These fringes are independent of the form, the size, and the orientation of the slit; they do not require a particular position of the screen or the slit, and the use of a lens is not indispensable. Their essential characteristic is that of exhibiting alternate colorations, which are sensibly complementary. In other respects they present the same aspect as those produced by one slit illuminating one grating. But the black fringes, which are very fine in the first case, are less sharply defined; the second phenomenon does not reproduce the delicate portions of the first, but shows only those bands which have a certain breadth. If the periods of the gratings are identical, the bands are sharply defined. If the illuminating grating has a number of slits per mm. equal to half that of the second, the colorations are the same, but less brilliant. On reversing the positions, the fringes become achromatic, owing to the superposition of the red and green bands of the two systems.—On the relation between the precipitation of chlorides by hydrochloric acid and the lowering of the boiling point, by M. R. Engel. To precipitate one molecule of a chloride from its saturated solution at 0° requires in the case of monovalent chlorides, one molecule of HCl, and in the case of divalent chlorides, two molecules. This is now proved also to hold good for temperatures other than 0°, and for double chlorides, like that of copper and ammonium, containing four atoms of chlorine and requiring four molecules of HCl. The molecular depression of the freezing point of solutions of the various chlorides was also investigated in its relation to the concentration. It was found that for the monovalent chlorides the molecular depression remains sensibly the same, varying between 35 and 40, but tends to reach twice that value for divalent, and four times that value for tetravalent chlorides. Hence at the freezing point of the saturated solution of alkaline chlorides, bromides, and iodides, there must be a relation between the atomic weights of the constituents of the molecule and the solubility.—On the variations of glycogeny in anthrax infection, by M. H. Roger. The glycogenic function remains intact during the first stages of anthrax infection. The amount of sugar contained in the blood is normal or slightly diminished. At the end of the disease, the hepatic glycogen rapidly disappears and a considerable hyperglycemia is produced.—Researches on the extension of the blastoderm and the orientation of the embryo in the ova of the Teleostea, by MM. R. Kœhler and E. Bataillon.—On the localisation of the active principle in the Cappardeæ, by M. Léon Guignard. The existence of special ferment cells is general in the Cappardeæ. By their morphological characteristics in the root and the stem they resemble those found in the corresponding organs of the Cruciferæ. In the leaf and especially the flower of the caper-tree their grouping is peculiar. All the reactions of their contents are those of myrosine. In the capers they are most numerous, and the glucoside is most abundant. The grains of all Cappardeæ, however, are relatively poor in ferment and in glucoside, and of their two constituents the embryo alone contains the ferment.—Sexual reproduction of the Ustilagineæ, by M. P. A. Dangeard.—On plane-tree honey, by M. Edm. Jandrier. During dry summers an exudation of varying consistence and aspect may be found on certain planes (*Platanus Orientalis*). It is sometimes dry and bright, sometimes pasty and yellowish, and contains, besides a small quantity of reducing sugar, probably glucose, about 80 or 90 per cent. of mannite, which may be extracted with the greatest ease by means of boiling alcohol and crystallisation.—Observation of an Aurora Borealis, by M. le duc Nicolas de Leuchtenberg. This was observed from the camp at Krasnoe Selo in the middle of July, about 10h. 30m. p.m. Its apex was situated very near the zenith, and seemed based upon a cluster of light vapours from which regular and regularly spaced bands proceeded, passing from white to a delicate pink and green, with a vibration resembling that exhibited by rarefied gases in Geissler tubes. It was seen to last about a quarter of an hour.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Solutions of the Examples in the Elements of Statics and Dynamics: S. Soney (Camb. Univ. Press).—An Elementary Treatise on Theoretical Mechanics, Part 1, Kinematics: A. Ziwet (Macmillan).—Text-book of Geology: Sir A. Geikie, 3rd edition (Macmillan).—Eskimo Life: F. Nansen, translated by W. Archer (Longmans).—Key to Carroll's Geometry (Burns and Oates).—The Shrubs of North-eastern America: C. S. Newhall (Putnam).—Handbook of Public Health and Demography: Dr. E. F. Willoughby (Macmillan).—An Elementary Treatise on the Geometry of Conics: A. Mukhopadhyay (Macmillan).—A Treatise on Hygiene and Public Health, Vol. 2, edited by Dr. T. Stevenson and S. F. Murphy (Churchill).—Vorlesungen über Maxwell's Theorie der Elektricität und des Lichtés ii. Theil: Dr. L. Boltzmann (Leipzig, Barth).—Healthy Hospitals: Sir D. Galton (Oxford, Clarendon Press).—Sporozoen als Krankheitserreger, Erstes Heft: Dr. A. Korotneff (Berlin, Friedländer).—Zoological Record 1892 (Gurney and Jackson).—Everybody's Letter Writer (Saxon).—The Out-door World: W. Furneaux (Longmans).

PAMPHLETS.—Reports of the Director of the Michigan Mining School for 1890–92 (Lansing).—Anleitung zur Krystallberechnung: Dr. B. Hecht (Leipzig, Barth).—Report on the Present State of our Knowledge respecting the General Circulation of the Atmosphere: L. T. de Bort (Stanford).—History of Slavery in Connecticut: Dr. B. C. Steiner (Baltimore).—Merchant Venturer's School, Prospectus 1893–94 (Bristol).—The Interdependence of Abstract Science and Engineering: Dr. W. Anderson (London).

SERIALS.—Mind, October (Williams and Norgate).—American Meteorological Journal, October (Ginn).—Boletin del Instituto Geografico Argentino, tomo xiv. Part 2 (Halifax, Nova Scotia).

CONTENTS.

THURSDAY, OCTOBER 26, 1893.

ANALYTICAL MECHANICS.

A Treatise on Analytical Statics. With numerous Examples. Vol. II. By Edward John Routh, Sc.D., LL.D., M.A., F.R.S. (Cambridge: at the University Press, 1892.)

THIS volume finishes Dr. Routh's work on the subject of analytical statics, the first volume of which was reviewed in NATURE, June 16, 1892. It contains, in three long Sections or Books, the subjects of Attraction, Bending of Rods, and Astatics, left over from Vol. I.

In Attraction a start is made with the Newtonian Law, and the Gravitation Constant is introduced.

The experimental redetermination of the numerical value of the Gravitation Constant is engaging the attention of Mr. Poynting (who has just been awarded the Adams Prize for his Essay on this subject) and of Mr. C. V. Boys. But we cannot hope to obtain, with the greatest refinements, an accuracy of determination within limits of error of less than one per cent.; the Astronomical Unit of Mass, defined in § 3, would be subject to the same limits of error, which are far beyond what is permissible in careful measurements with the Balance.

The only reason for the introduction of the Astronomical Unit of Mass is to save the trouble of writing down k, the Gravitation Constant, in our equations; but we agree with Prof. Minchin, in his Analytical Statics, in thinking that it tends to clearness if we take the trouble to write k in its proper place, so as always to measure m in such well-determined units as the gramme or kilogramme.

Nowadays the theorems of Attraction receive their most appropriate interpretation, analytical and experimental, from the subject of Electrostatics; the theorems on the Potential of Laplace, Poisson, and Gauss, on Tubes of Force, Green's Theorem, Inversion, Laplace's Functions, and on the Attraction of Ellipsoids of Chasles, all present themselves as fundamental in the Electrostatical chapters of Maxwell's "Electricity and Magnetism;" insomuch that Maxwell ventured to present a demonstration of some of the most abstruse analytical results of Laplace's Functions, founded on physical principles of Electrostatics, and thereby excite the ire of certain mathematicians of the purest proclivities.

For instance, the complicated theorems on Centrobaric Bodies, discussed in §§ 111, 116, become self-evident when interpreted as the analogues of the electricity induced on an uninsulated closed surface by an electrical point in the interior. The external electrical effect being zero, the potential of the induced electricity is equal and opposite to that of the point, and therefore the surface has an electrical coating which is centrobaric, the function which represents the superficial density being *Green's Function* for the surface and the point.

If the dielectric in the interior is stratified, an electrical concentration is distributed throughout the space, and thus the analogue of the centrobaric body is obtained; but incidentally the electric analogy shows that the strata of equal density in the centrobaric body are each separately centrobaric, so that the centrobaric body is built up of centrobaric shells. The sphere is the homogeneous centrobaric body, as Newton showed in the "Principia"; and an application of Sir W. Thomson's powerful geometrical method of electrical inversion deduced the fact that a solid sphere whose density varies inversely as the fifth power of the distance from an external point O′ is centrobaric with respect to the interior inverse point O. So also for a spherical shell, either this or composed of a series of concentric strata; and this by inversion leads to the theorem that a shell bounded by two excentric spheres of which the limiting points are O and O′ is centrobaric if the density at any point P in it is

$$\mathrm{OP}^{-5}\phi(\mathrm{OP}/\mathrm{O'P}/)$$

The discovery of Green's function for a given surface, or rather the discovery of surfaces for which Green's function can be assigned, is one of the most difficult and baffling of modern analysis; and it has so far only been effected for some few simple cases.

The British Association met recently at Nottingham, the birthplace of George Green in 1793. There must be people still living there who remember him, and could supply now, before it is too late, some interesting details of the causes which led to the development of his wonderful mathematical genius, at a time too when little encouragement was vouchsafed to such abnormal proclivities. In France a statue would long ago have arisen in his honour; but at least an interesting paper on the subject of Green's life could be communicated to Section A.

The theorems of Chasles and Maclaurin on the attraction of homœoids and focaloids are fully discussed in §182; the homœoids receive ample illustration in electrical phenomena; but Maclaurin's theorem on the attraction of confocal homogeneous solid ellipsoids is rendered more convincing by supposing the smaller confocal to be scooped out of the larger so as to form a thick focaloid, the matter which is scooped out being condensed homogeneously with the rest of the substance. The effect of this operation is to leave unaltered the external potential, and the original matter may thus ultimately be condensed into a thin focaloid, in which the thickness is inversely proportional to the perpendicular on the tangent plane; and this focaloid will have the same external equipotential surfaces as the solid ellipsoid.

Part ii., on the Bending of Rods, does not assume any new experimental knowledge beyond that of the proportionality of the curvature to the bending moment, an assumption which we know from Prof. Karl Pearson's "History of Elasticity" to be only a first rough approximation to the truth.

The analytical consequences of the hypothesis are, however, very elegant and instructive, and Dr. Routh has brought together an interesting collection of illustrative examples.

He does not, however, develop the elliptic function solution of the plane Elastica or associated Lintearia, curves which can now be drawn with great accuracy and rapidity by Mr. C. V. Boys's scale. He also restricts himself to the uniform helix in the tortuous Elastica; but the student who wishes to pursue this branch of the subject to its fullest development must consult vol. ii. of Mr. Love's "Elasticity," which has recently appeared.

Kirchoff's Kinetic Analogue between this Elastica and the motion of a Top, makes the same analysis serve for both; thus, as pseudo-elliptic solutions, we may mention that tortuous Elasticas are given by:—

$$\text{(i.)}\ r^2 e^{2i(\psi+ps)} = \sqrt{\{r^2 - \tfrac{1}{4}c(1-4c)a^2\}}\sqrt{\{r^2 + \tfrac{1}{4}(1-2c)(1-4c)a^2\}} + \tfrac{1}{2}i(1-4c)a\sqrt{\{\tfrac{1}{2}c(1-2c)a^2 - r^2\}};$$

$$\text{(ii.)}\ r^3 e^{3i(\psi+ps)} = \{r^2 + (1-c)(2-3c)a^2\}\sqrt{\{r^2 - (2c-3c^2)a^2\}} + i(2-3c)\sqrt{\{-r^4 - (1-c)(1-3c)a^2r^2 + (1-c)^2(2c-3c^2)a^4\}};$$

corresponding to parameters $\omega_1 + \frac{1}{2}\omega_3$ and $\omega_1 + \frac{2}{3}\omega_3$ of the related Elliptic Integrals of the third kind.

Here a determines the scale of the figure, and c is an arbitrary parameter, upon which p depends; and it is curious that in case (ii.) the value $c = \frac{1}{3}$ makes p vanish, and then $\omega_3 = \sqrt{(-3)}\omega_1$.

Other interesting applications of the Theory of the Bending of Rods, requiring Bessel Functions, are the investigations of the greatest height consistent with stability to which a vertical wire or mast can be carried, or to which a tree can grow, without drooping over under its own weight; we can thus supply the analysis required in the old German proverb, quoted by Goethe, "Es ist dafür gesorgt, dass die Baüme nicht in den Himmel wachsen."

The third part, on Astatics, is intimately bound up with the distribution in space of Poinsot's central axis for a system of forces; or with Sir Robert Ball's investigation on Screws. A great analogy exists with the analysis required in the distribution of principal axes in space. A problem which might well find a place here is, "The moment of inertia of a body of mass M about any generating line of the hyberloloid of one sheet

$$\frac{x^2}{a^2+\mu} + \frac{y^2}{b^2+\mu} + \frac{z^2}{c^2+\mu} = 1,$$

confocal with the ellipsoid of gyration

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1$$

is constant, and equal to

$$M(a^2 + b^2 + c^2 + 2\mu)."$$

Dr. Routh has now completed his work on "Analytical Statics," and the two volumes form an indispensable addition to the library of the mathematical student.

A. G. GREENHILL.

MOLESWORTH'S POCKET-BOOK.

Pocket-Book of Useful Formulæ and Memoranda for Civil and Mechanical Engineers. By Sir Guilford L. Molesworth, K.C.I.E., M.Inst.C.E., and Robert Bridges Molesworth, M.A., Assoc.M.Inst.C.E. 23rd edition. (London: E and F. N. Spon, 1893.)

OF all the many books published for the assistance of engineers generally there is none so well known to the profession as "Molesworth." This pocket-book is to be found in the possession of every engineer, and rightly so, because it is certainly the most useful and accurate of the many to be obtained.

Any work which has reached the 23rd edition requires no praise to verify its position. This edition is said to contain new and important information on recent engineering and industrial developments, many of them entirely new, and much of the matter in previous editions has been revised. "Molesworth" treats with nearly all the various branches of engineering, and so extensively has this been carried out that it is impossible to notice but slightly its contents; besides the many purely technical formulæ there is to be found a collection of most useful tables applying generally to engineering. There are, however, a few mistakes in the mass of matter brought together in this book, and in some instances statements are made which would have been better omitted.

On page 254 we read that Vickers' straight steel axles should have an ultimate tensile strength of not more than 23 tons per square inch, and that this test can only be made by destroying the tested axle. Crank axles should also have a maximum tensile strength of 23 tons. There is either a typographical error or gross mistake in this statement. Had the maximum limit been given 33 tons it would have been nearer the mark; 23 tons is absurd. Probably the best tensile tests for steel axles would be 30 tons per square inch, 25 per cent. extension measured over a length of three inches, and 40 per cent. contraction of area at point of fracture. The author omits to state that straight axles are tested under the tup, and that it is this test which destroys them. It is usual to take the tensile sample from this axle. Again, in the tests for steel tyres given on page 255, we notice that a tensile strength of 47 tons is required, but no extension or contraction of area is specified. This is all very well, but tyres have been known to stand the tup test and give the proper tonnage in the tensile test, still the extension has only been 5 to 8 per cent. on three inches, when 16 per cent. is the lowest limit safety demands.

On p. 410, under the head of workshop recipes, there are several mixtures given for case-hardening of wrought iron. The first recipe is used by a few people, but the majority use ordinary charcoal mixed with about 2 per cent. of soda ash. This gives a very uniform and close-grained casing. The author gives no time-allowance for the articles to remain in the furnace; this is all-important, because the time governs the depth of the casing. Further on, at p. 418, we find some recipes to prevent the incrustation of boilers. One cannot help being amused to discover in "Molesworth" of 1893 that potatoes, $\frac{1}{50}$th the weight of water in the boiler, when put in prevent adherence of scale. Twelve remedies are given, but the only one a man having any regard for his boiler would use is that of frequent blowing off.

When dealing with the question of the proportions of locomotive boilers on p. 453, the statement is made that—(1) no fixed rule can be established as to the best relative proportions of grate, fire-box, and tube surfaces. (2) Length of tube does not affect economic result. (3) Diameter of tube is a matter of indifference.

These conclusions are, to say the least of it, very dogmatical. Given the class of fuel to be consumed and the work to be done, then the question of the design of boiler is not very difficult, and the general practice in this respect may be said to be uniform. This practice is certainly approaching a fixed rule. Given the conditions, the design, or we should say the proportions, becomes an easy matter to designers worthy of the name.

We leave our readers to form their own opinions upon conclusions Nos. 2 and 3. It is a pity they are to be found in "Molesworth," because they may lead students and others to form the opinion that these most important details are matters of no consequence. The compound locomotive naturally is included in the new matter added to this edition, and being of great interest to all connected with railways, we expected to find the subject thoroughly up to date. In this we are disappointed; two-thirds of a page is considered ample space to discuss this important question, the other third being taken up with a few lines on American locomotive practice! American locomotive engineers do not consider the two-cylinder arrangement for compounding "most suitable," nor does Mr. F. W. Webb, the able locomotive superintendent of the L. and N.W. Railway. Surely these two subjects are worthy of more space and better treatment.

On p. 466 we notice a formula having reference to the blast pipe of locomotive engines, applying in particular to the exhaustive power of the pipe, as the efficiency of a blast pipe seems to depend more on its vertical position in the smoke-box than on anything else. This fact might have been noted with advantage.

The rule given on p. 499 for the safe load on locomotive springs, by Mr. D. K. Clark, is found to be rather excessive; the constant 11·3 can be increased with advantage to 15, the result thus obtained being the actual load to be carried. Notwithstanding these few weaknesses, Molesworth's Pocket-Book is, without doubt, incomparably the best of its kind; and so accustomed have engineers, and particularly draughtsmen, become to the continual use of this valuable book that most of them would be now really lost without it.

This book is clearly and well printed, nicely got up, and is a credit to all concerned in its publication.

THE AMERICAN CATALOGUE OF MEDICAL LITERATURE.

Index Catalogue of the Library of the Surgeon-General's Office U.S. Army. Vol. xii. (Reger—Shuttleworth), pp. 1004, 1892, and vol. xiii. (Sialogogues—Sutugin), pp. 1005. Imp. 8vo. Washington, (Government Printing Office, 1893.)

IT is a great pleasure to all who are interested in any form of library or literature to observe how punctually, year by year, these magnificent volumes appear, and show in a very practical way how American enterprise can deal with old-world questions of gathering together and keeping up a collection of books that is superior in its own department to any other, and which has been got together in little more than thirty years. What is framed as an Index Catalogue of the Library of the Surgeon-General's Office at Washington constitutes in effect a dictionary of all medical and surgical literature, ancient and modern, with very few *lacunæ;* the entries under authors' headings have now reached 240,007, and under subject-headings 539,927; and the attempt which at first sight may well have seemed too ambitious —viz. to catalogue under subject-headings all the signed articles which touch on medicine which exist in the periodical publications of all languages, as well as to cross-catalogue all medical books and pamphlets of the world under both author and subject-headings—has turned out perfectly successful. In the first eleven volumes there were mentioned 3,929 periodical publications which were thus treated; in the two more volumes which are before us there are 341 additions, and though some of the older ones may have died out, yet the labour remaining is obviously no light one. The thirteenth volume brings us within sight of the end, and it is probable that two years more may finish the first edition of the catalogue; yet it cannot but be that some provision, by supplement or otherwise, must be made for the literature which during fifteen years has been accumulating under the headings of the earlier volumes, and some arrangement must be made for the literature of the future. From the monthly issues of the *Index Medicus,* which is a catalogue issued by Mr. Billings, on similar lines, of purely contemporary medical literature, we may estimate that the sum total of titles of additions to the world's medical literature would amount to about one such volume as the present every three years, which leaves us no doubt that the successors to Mr. Billings, the present librarian, will have occasion for all the indomitable activity and accuracy he has shown. In the twelfth volume, considerable use in various quarters has enabled us to find only one trifling misprint of a well-known physician's initials (xii. 449), but accuracy in such details is indispensable when we have to do with 136 authors of the name of Richter, 227 of the name of Smith, and 240 of the name of Schmidt. The student may be overwhelmed at first by the 39 imperial 8vo. pages that are required for a closely-printed catalogue of the titles of the literature of scarlet fever, but he will find that 46 pages are needed for rheumatism, 63 for small-pox, and 102 for surgery. Under these large headings the sub-indexing is excellent. The great importance of such a classification under subject-headings should never be lost sight of in a catalogue which deals mainly with matters of observation and natural science, for, in a large majority of cases, the importance of the record depends more on the observation than on the observer, and the student for whom all these volumes are such an invaluable help to knowledge is much more likely to be wishing to pursue an inquiry on a particular subject, regardless of those who wrote on it, than to trace out the works of a particular author regardless of what he wrote upon. However, Mr. Billings is extremely liberal to him, and gives him an excellent chance of doing both, of seeing all the vast mass of signed periodical literature as well as the books written on the particular subject, and also of seeing a list of all that each author has written with the exception of the articles in periodical literature that he has not republished, and he will find that many authors have republished in pamphlet form all that is worth reading.

The task of classification under subject-headings of all literature, both periodical and other, has been felt too enormous for any first-rate general library, and, so far as we know, has only been attempted by the Germans over comparatively small branches of knowledge, *e.g.* Carus and Engelmann's *Verzeichniss der Scriften über Zoologie welche in der periodische Werken enthalten.* The Royal Society's "Catalogue of the Scientific Papers contained in the Scientific Periodicals" (8 vols. 4to) contained only a list under authors' headings of the publications between

1800 and 1873, and did not attempt to deal with any subject-headings, or any of the past history of the subjects as Mr. Billings has done in his rich and varied Index Catalogue of very nearly all the Medical Literature printed between the fifteenth century and the present day. A. T. MYERS.

OUR BOOK SHELF.

Lehrbuch der Botanik nach dem gegenwärtigen Stand der Wissenschaft. Bearbeitet von Dr. A. B. Frank. Zweiter Band: Allgemeine und Specielle Morphologie. 8vo, 431 pp. with 417 Woodcut Figures in the text, and an Index to Volumes I. and II. (Leipzig: Wilhelm Engelmann, 1893.)

THE first volume of this work, dealing with histology, anatomy, and physiology, was noticed in NATURE, vol. xlvi. p. 610, where some facts may be found connected with its history, scope, and arrangement. The present volume is concerned with general morphology and special morphology, or classification. It is, on the whole, exceedingly well compiled, and, as was said of the first volume, it is written in the clearest and easiest style, with no superabundance of words, such as often render German text-books unnecessarily difficult to the beginner. The illustrations (upwards of 400) are for the greater part borrowed from the works of Sachs, Gœbel, Schenk, Prantl, Pringsheim, Hanstein, Schimper, Strassburger, Hofmeister, De Bary, Tulasne, Bornet, Brefeld, Woronin, and other specialists, but chiefly from the first. These are all duly acknowledged, and, as the author states in his preface to the first volume, he has made the best selection he could, and he has used these familiar figures because he could not substitute better ones. This is, of course, true; yet we put it on record to inform the student that he will find little that is original in this way. General morphology occupies fifty-four pages, under four heads, namely: discrimination of forms in the vegetable kingdom, directions of growth, general laws of the relative positions of the members of the vegetable body, and origin of the members of the vegetable body. The remainder of the volume is devoted to special morphology, or systematic botany; but the large groups are somewhat unequally treated, 179 pages being devoted to cryptogams, as against 140 to phanerogams. Indeed, too much has been attempted in the space. For instance, the very brief diagonses of the natural orders given at the end of this volume can be of little service to the beginner. Few of them exceed six lines, and many of them are even less, consequently the characters given are often insufficient to include half of the genera. Generally speaking, they are correct as far as they go, but they are often not sufficiently comprehensive. We have said that this is an excellent book, yet here and there one stumbles upon statements that cause no little surprise. Thus the pictures of Nepenthes, Sarracenia, and Cephalotus are described indiscriminately as transformed terminations of tendril-like continuations of the leaves. Then with regard to the bibliography, the selections are by no means critical, and sometimes defective, especially in foreign literature. The indexes, of which there are three, are sufficiently copious. There is an index to the woodcuts, an index to the subjects, and an index to the plant-names. When will authors learn that one general index is preferable to a number of classified references? In this work it would have been much more convenient to have had an index to each volume.

The Elements of Natural Science. Part III. Natural Philosophy. By Dr. H. Wettstein. (London: O. Newmann and Co., 1893.)

THE German edition of this book is obligatory for all the secondary schools of the canton of Zurich, which partly accounts for the fact that more than seventeen thousand copies have been sold. It is doubtful, however, whether the translation will be so widely appreciated in England. There are already many excellent introductions to science covering practically the same ground as Dr. Wettstein's work. In one feature only is the book superior to the majority of those produced in England; viz. in the abundance of illustrations. As a rule, our text-books of science are very poorly off in this matter, whereas Ganot, and Deschanel, and the book before us, are brightened considerably by the insertion of numerous illustrations.

When we say that in the 138 pages of the book the sciences of mechanics, sound, light, heat, electricity, and magnetism are treated, it will be at once understood that the descriptions are of a rather sketchy nature. In spite of this, however, the book will give its readers a good grounding in the principles of physical science. Though most of the text can be easily comprehended by the average pupil, there are portions which should hardly be inserted without explanation. Thus, on p. 44 we read: "The atmospheric pressure carries our legs and arms, for the condyle of the femur fits air-tight into the acetabulum of the pelvis, and likewise the condyle of the humerus into the articular cavity of the shoulder-blade." And it is misleading to say: "The complete spectrum of sunlight consists of three parts—*the heat spectrum, the light spectrum, and the chemical spectrum*" (p. 71). The table of spectra given in the frontispiece is poor, one of its defects being that the solar spectrum only differs from the spectrum of Sirius by the addition of the three lines A, a, and B. With this exception, however, all the illustrations are very clear and accurate.

A Short Course in the Theory of Determinants. By L. G. Weld. (London: Macmillan, 1893.)

WE have read Prof. Weld's book with much interest, for though there are few, if any, novel results brought forward, he has certainly attained the goal he set before himself, and has developed the theory in a very simple manner. Some of the methods he has employed are new to us. The greater part of the work requires little beyond an intimate acquaintance with the principles of algebra as given in the ordinary school text-books. To confine the treatment within very moderate limits, there is no application of determinants to analytical geometry, but many of the more important algebraical applications find a place. After treating with sufficient detail of the origin and notation of determinants, our author gives a general definition of them, and enumerates and proves the more useful of their properties, and then touches lightly upon their applications to elementary algebra, *i.e.* to matrices and Sylvester's and Euler's methods of elimination. In Chapter vi. he briefly discusses the multiplication of determinants and reciprocal determinants. The last three chapters give a brief account of special forms, and of linear transformation. The text is very clearly printed, and we have detected but few trivial errors. There is a good store of examples, some of which appear to us to be rather "stiff." Due acknowledgment is made in the preface to the sources from which results have been derived.

A Practical Treatise on Bridge Construction. By T. Claxton Fidler, M.I.C.E. Second Edition, enlarged and revised. (London: Charles Griffin and Co., 1893.)

THE first edition of this book was reviewed at length in NATURE, vol. xxxviii. p. 2. Since then the Forth Bridge has been completed, and great advance has been made in the manufacture of steel.

The principal criticism to be added to the former review is that the author should add some remarks on the method of erecting a bridge, large or small. As it is, the structures are described as if they dropped down ready made from the sky into their appropriate place.

Many superior designs could at this rate be made for the Forth Bridge; but then this ignores an important controlling element, that the bridge was to stand, not only when completed, but at every intermediate stage of the erection.

Even the operation of hoisting or rolling into place a forty-foot girder is not a simple matter; during the process the ordinary stresses are mostly reversed, and the structure runs the risk of "cockling."

We find no mention of the Tower Bridge, the most important experiment of a drawbridge *à bascule*. G.

The Amphioxus and its Development. By Dr. B. Hatschek. Translated and edited by J. Tuckey. (London: Swan Sonnenschein and Co., 1893)

THIS is a translation of Dr. Hatschek's well-known paper on the subject published twelve years ago. It will no doubt enable those who cannot read German to follow Dr. Hatschek's statements. But unless the rest of the translation is more accurate than that of the title, readers will be deceived and disappointed. This book is not correctly called "Amphioxus and its Development." That is a salesman's title. There is nothing in it about Amphioxus, except an account of the earlier part of the development. The important facts of the larval development discovered by Willey, as well as the adult structure, are not dealt with. The original plates have not been reproduced in this translation, but very small and often obscure reductions of them are substituted.

E. R. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Use of Scientific Terms.

I AM glad that so distinguished a physicist as Dr. Lodge has found certain matters relating to the history of physiology, which I discussed, I fear very imperfectly, in my Nottingham address, to be of sufficient interest to induce him to read and criticise it. Fully appreciating the geniality with which his criticisms are expressed, I will ask your permission to comment on one or two points in his letter, which may not be uninteresting to the readers of NATURE.

One of the principal objects which I had in view in my address was to promote that intercommunication between the physical and physiological sciences which Dr. Lodge thinks so desirable, and I am no less sensible than he is that this solidarity is much impeded by inconsistency in the employment of words. Your correspondent avers that whereas the language of Physics consists in "simple English phrases" and "common words made definite by connotation," our biological words are "polysyllabic," and our modes of expression as unlike those of daily life as can be contrived. We say "devitalising," for instance, when we mean killing, just as the chemist says "desiccating" when he means drying.

It is difficult to express the complicated relations which exist between the phenomena of life without using terms which are themselves complicated. Thus, I venture, notwithstanding Dr. Lodge's good-natured pleasantry, to think that the word "chemiotaxis," bad as it may be, serves better to express the little that we know about the "particular go" of certain processes than any simple English phrase we could substitute for it.

Two words, "life" and "energy," are specially referred to by Dr. Lodge as examples in illustration of the inconveniences which are to apt to arise from their improper use. In Physiology the word "life" is understood to mean the chemical and physical activities of the parts of which the organism consists together with their co-ordination—not the processes only, nor their co-ordination only, but both at the same time. Dr. Lodge uses the word life without making it "definite in connotation," but from what is said about it, it is evident that the life which he has in view is not made up of processes, but merely consists in their co-ordination or adaptation for the purposes of the organism; for it is defined as the "power of *directing* (the italics are mine) energy into otherwise unoccupied channels." This being understood, all that Dr. Lodge says about life, and particularly his statement that it is *not* a form of energy, seems to me to be in accordance with the views that I endeavoured to set forth in my address. The only difference, therefore, that exists between us relates to the sense in which the word life is to be used for scientific purposes. Next follow some trenchant observations as to the misuse of the word "energy." I do not think that I am accused of such misuse. Nevertheless it may be useful to note that in referring to the sense in which J. Müller and his illustrious pupil had used the term "specific energy," it was expressly stated that their use of it was in a sense entirely different from that in which it is employed in physical science; and further, that the words quoted from the "Physiological Optics," viz. "energies of the nerves of special sense," were written in 1886, not "long ago," as Dr. Lodge suggests.

I can assure your readers that to the best of my knowledge the word "energy" is never used in the old sense by physiological writers, excepting, so to speak, between inverted commas; and with reference to the historical importance of Müller's doctrine, and still more of Helmholtz's earlier physiological writings, the words "normal activity," or others of similar import, are substituted for "specific energy," not as necessarily meaning anything quantitative, but simply the mode in which the organ normally reacts.

To the suggestion that "subjective light" should in future be designated by an impressive-looking word beginning with *photo* and ending with *taxis*, I have no objection to make, excepting that it might turn out to be rather sesquipedalian. May I add, that I hope to have the opportunity of recurring to the subject of the vision of the totally colour-blind.

J. BURDON SANDERSON.

The Thieving of Antiquities.

A RECENT case, which has occupied some space in NATURE, raises much larger issues than the character of individuals, and issues which must be faced sooner or later.

The present conditions of the laws and practice regarding antiquities is most unhappy, both in the interests of science and in the interests of museums. Two matters require much revision: (1) The modes of excavating; (2) the laws regarding excavation and exportation.

As to the mode of excavating it is still generally the custom to leave much in the hands of native overseers, and often the European in charge does not live on the work. Until it is recognised that it is unjustifiable to disturb antiquities without recording everything that can be observed, we shall remain in the state of mere plunderers, without a claim much higher than that of the treasure-hunting natives. In Egypt, hitherto, nearly all official excavations have been made by trusting entirely to uneducated and dishonest native overseers; and while the laws are strict concerning Europeans working, the natives plunder almost at their will under one pretext or another. With suitable regulation it has been proved practicable to entirely excavate a site without any loss or pilfering of the smallest objects by the natives; and such excavation, entirely under trained and educated observers, either native or foreign, should be the aim in all future work.

But in the matter of the legal position it is far more difficult to reach a satisfactory basis. Baldly stated the case stands thus. Every country in which there is anything much worth having, stringently prohibits exportation and excavation; and nearly all the growth of museums of foreign antiquities is in direct defiance of the laws. Most countries are engaged in thieving from others on a grand scale, by various underhand agencies; a form of thieving which is as much tolerated by public opinion as smuggling was in former days. According to law, no antiquities of any kind can possibly leave Turkish or Greek territory, and nothing that is of great importance can leave Italian or Egyptian territory. Yet museums grow.

The actual course of affairs is that some private agent, or museum official, hears of something important, and buys it up in order to smuggle it for the museum in which he is interested. Sometimes museum officials go on missions to collect, or to excavate in accordance with the laws, while what they obtain is smuggled out in defiance of law. This is going on yearly, and will go on till some better system is established. Meanwhile all information concerning such discoveries has to be suppressed; and the most important acquisitions of museums are a matter which cannot be published, or even talked about in detail, while official papers have to be treated as secret archives.

In England the Government is a hindrance rather than a help to a better state of things. France and Germany ask other powers in a straightforward way for presents of antiquities by diplomatic channels; and they often get what they want, as we did in the days of Lord Stratford de Redcliffe and Sir Henry Layard. But recently English diplomacy has, on the contrary, repeatedly thrown away what rights Englishmen might claim concerning antiquities, in order to gain petty advantages which diplomatists were capable of understanding.

The work which has been done in Egypt by the Exploration Fund and myself, at least shows that such an unsatisfactory state of things is not unavoidable. The Egyptian laws are administered with more sense than such laws in other lands, and with a little diplomatic protection the position would be all that could be reasonably wished. For many years large excavations have been made openly, and with complete freedom, by Englishmen; nothing has been lost, either of objects or information, owing to surreptitious methods; all that has not been most essential for the country itself has been openly brought to assist study in England, and the fullest statements can be openly and honourably made on the subject. Meanwhile objects smuggled by officials have to be kept quiet, and lose whatever scientific value their record might have possessed.

Until our Government sees its interests in backing up work for its museums by honest methods, and straightforward dealing, we shall continue to lose the greater part of the scientific value of museum acquisitions, and to have a seamy side to our administration which is more discreditable than those personal questions that have lately been raised.

W. M. FLINDERS PETRIE.

University College, London, October 10.

The Glaciation of Brazil.

DR. WALLACE'S pointed reference to myself in this week's NATURE induces me to send you these few lines.

It has been said by more than one critic of my book on the "Glacial Nightmare" that in some cases I was merely slaying the slain, and notably in regard to Agassiz's views about the glaciation of Brazil. It has been overlooked that Agassiz's experience and authority on glacial matters were unrivalled, and that he had written on this very question: "An old hunter does not take the track of a fox for that of a wolf. I am an old hunter of glacial tracks, and I know the footprint whenever I find it."

Again, Dr. Wallace, whose knowledge of the tropics is so profound, had written: "Professor Agassiz was thought to be glacier-mad, but if we separate his theories from his facts, and if we carefully consider the additional facts and arguments adduced by Prof. Hartt, we shall be bound to conclude that however startling, the theory of the glaciation of Brazil is supported by a mass of evidence which no unprejudiced man of science will ignore merely because it runs counter to all his preconceived opinions." Again he says: "It can hardly be maintained that the discoverer of glacial phenomena in our own country, and who has since lived in such a preeminently glaciated district as the Northern United States, is not a competent observer; and if the whole series of phenomena here alluded to have been produced without the aid of ice we must lose all confidence in the method of reasoning from similar effects to similar causes, which is the very foundation of modern geology."

Lastly, Mr. James Geikie, in his second and revised edition of "The Great Ice Age," quotes Agassiz's conclusions without a word of protest or warning (*op. cit.* 484–5).

With these strongly expressed views before me, it was impossible to ignore the issue, and it can hardly be said I was slaying the slain in criticising those who believed in tropical glaciation.

I did not then know that in his subsequent work on Darwinism Dr. Wallace had, with that candour which makes his works so valuable to some of us, qualified and partially withdrawn his previous conclusions on the subject, a fact which he again emphasises in his letter to you. With this letter *cadet quæstio*, I know no one now who is willing to support Agassiz's theory, and we may take it to be dead. *Requiescat in pace.*

Meanwhile, however, let us do justice to those whose observations and logic have dispelled one phase at least of the glacial nightmare. Dr. Wallace attributes this to his friend and correspondent, but the work had already been done, and amply done, by others, as I tried to show in my recent book. In it I have quoted largely from the admirable remarks of Prof. Orton, Dr. Ricketts, M. Crevaux, and last, but not least, Prof. Hartt himself, who as far back as 1871 had given up Agassiz's views in regard to the Amazonian glacier (see *American Journal of Science*, 3rd ser. vol. i. pp. 294–5).

When we have got rid, however, of Agassiz and his Amazonian glacier, we have not got rid of all our difficulties. While we cannot accept the notion of tropical ice-sheets, we have still to explain the existence of erratic phenomena in the tropics, such as those described by Schomberg in Guiana, by De la Beche in Jamaica, by Blandford in Southern Persia, by Chardin in Media, by Belt in Nicaragua, and by Hartung in the Azores. There seems some difficulty in explaining these phenomena without invoking the former existence of local glaciers in parts of the tropics where they no longer exist, and also the occurrence of large diluvial movements there. I should be greatly indebted to Dr. Wallace, and so would others, for his views on this subject. There remains another and a more critical difficulty which I must reserve for another letter. In conclusion he will permit me to thank him for his very valuable and courteous letter.

HENRY H. HOWORTH.

30 Collingham Place, Cromwell Road, S.W.

The Glaciation of Brazil.—Scintillation of Stars.

A VERY cursory examination of the gneiss rocks about Rio de Janeiro—particularly the Corcovado—will show how the rock breaks up. In some places it comes off in great flakes like the coats of an onion, and the edges of these flakes are quite friable, and can be reduced to fine grains between the fingers. In many places it is found quite crumbled up by the weather, and down the coast towards Santos fine grains of these rocks can be found in the soundings at some distance from the land.

It is somewhat singular that observation has led me to a contrary opinion to M. Dufour in the scintillations of stars (NATURE, October 19). My attention was first drawn to the phenomenon by an old and experienced sailor, a native of the Western Islands, and a most clever weather prophet. I have constantly observed at sea that steadily-burning stars indicated calm, fair weather, and the more they twinkled the worse the weather was likely to be. The forecast given by this variation in scintillating was almost invariably correct in the high latitudes, though it failed sometimes in the tropics.

DAVID WILSON BARKER.

The *Worcester*, Greenhithe.

The Summer of 1893.

IN his letter in NATURE of August 31, Mr. W. B. Crump explains how the weather of the year has influenced the times of the flowering of the Halifax flora; and it may be of some interest to offer a note on the blossoming of a few common plants, trees, and bushes around Worcester.

The cardamine blossomed on April 16, herb Robert on the 16th, the oak on May 5, the elderberry on the 10th, the purple orchis on the 13th, and bear's garlic on the 13th also.

In this part of England field blossoms form an important factor in cottage economy. The harvest of this flora begins in spring with the primrose, the violet, and the wild daffodil, the latter here called the Lent lily. This season the Lent lily blossomed in March, as did the primrose and violet. Of late years these flowers have acquired a commercial importance, and engage, especially the former, a multitude of pickers and packers, lending life and colour to lonely railway stations. During the season dealers station in suitable country habitats agents who collect the flowers gathered by the pickers, and in large hampers despatch them to destinations all over the kingdom. This year the daffodil yielded less abundantly than usual.

Next to these blossoms follows the cowslip crop. This, for the sake of the pips, which, at 1*s.* a peck, are in demand at the British wine makers, is collected largely by cotters' children.

Owing to the drought the crop, greatly to the distress of poor folk, proved an utter failure. Happily the wealth of the season's blackberry crop atoned in some measure for the cowslip failure.

The modern taste for cut flowers has given a commercial place also to the blossoms of the wood anemone, the marsh marigold, the ladies' smock, and the yellow iris.

The apple, pear, and plum crops were excellent. In some plantations the gooseberry crop, through the ravages of the scourge known as the red spider, was destroyed, and the bushes killed.

The hop crop was good and great, the bulk being of a quality rarely, if ever, surpassed. As early as July 28 two pockets reached Worcester market; a date, save one, the earliest on record. Some twenty-four years ago—I cannot put my hand on the exact date—a pocket was delivered in this market on July 26.

On August 8 this season picking began to get general. On September 8, some days earlier than picking usually commences, many planters had finished.

On September 19, in ordinary years, hops begin to reach the market. This season much before that date the public warehouses were filled with new hops. The season being in advance of the hop requirements of the brewers, merchants did not attend to buy. For all this, waggons heavily laden with towering loads of hops came pouring in, and not only were the public warehouses filled, but the floor spaces of the Shirehall, the Guildhall, and the Gymnasium were packed.

The most notable feature of the year, doubtless, is the circumstance that during the latter part of July, as well as through the month of August, and down to the present date, there was, and is, a second leafing, blooming and fruiting of fruit and forest trees, and blossoming of the spring and summer flora.

In Paris the horse-chestnut trees blossomed and leafed afresh, as happened with many horse-chestnut trees in Cambridgeshire. In Kent orchards again put forth blossoms, while the ripening fruit of the year loaded the boughs. As far north as Manchester, and likewise near Wigan, the rhododendrons blossomed again. Throughout England many fruit trees are in second bearing. In the avenue of lindens in the New Road, in this city, many of the trees are garnished with new foliage of the exquisite vivid green tincture of spring; the leaves have attained full size. Strawberries ripe and of large size (5 inches in circumference) are common over a wide area of England. At Redruth, Cornwall, primroses, gentians, and golden chain, and most of the early spring flowers are again in splendid blossom; and there also fruit trees, while in full crop, are again in rich bloom.

In the Cottenham district of Cambridgeshire a second crop of various kinds of fruit is being gathered. Green gooseberries have been secured during the last few days from one of the gardens; raspberries have in several places blossomed again, and produced finer fruit than the first crop; while apple-trees also show a rich second bloom. In North Wales dog-roses, honeysuckle, and foxgloves are again in splendid bloom. In Worcestershire the midsummer flora is again in flower. Generally the late potato crop is growing again, and great deterioration of the tubers ensues. In Tenbury, Worcestershire, many of the potato tubers are flabby, as though scalded, and when boiled turn black and become nauseous, and the growers are wondering what is the matter.

At Médoc the vintage began on August 20, a month anterior to the usual date. For generations such an early date has not been known. The Girondins say the crop is splendid; sufficient casks for the crop are not procurable.

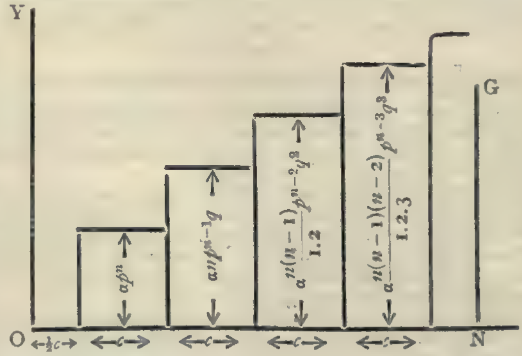
Here, in spite, or perhaps in consequence, of the drought, the familiar wayside wilding, the ladies bed straw, formed (in meadows put up for mowing) a great part of the crop, and, flinging lavish perfume around, lined every wayside hedgerow. The humming-bird moth, of which the bed straw is a food plant, was more common than ever before within my rather long experience. At the end of August, a month before the usual time, the thousand of Irish harvestmen left our shores for home.

The summer of 1818 resembled greatly that of the present remarkable year.

Worcester, September. J. LLOYD BOZWARD.

Asymmetrical Frequency Curves.

SOME six years ago (September 1, 1887) Dr. Venn wrote to you pointing out the asymmetrical character of certain frequency curves occurring in physical and biological measurements. I have recently obtained a generalised form of the probability curve which fits with a great degree of accuracy such curves, and propose to discuss it at length shortly. Meanwhile I wish to point out that an asymmetrical *point* binomial may be readily fitted to such curves, although not with the completeness of the above referred to continuous curve. Let n be the number of events in a group, p the probability for single event, and q that against it; let c be the horizontal space selected as the basis of each rectangle forming the point binomial, and let α be the total area. Then we have the following diagram given by the point system:



where the successive heights are the terms in

$$\alpha\left(p^n + np^{n-1}q + \frac{n(n-1)}{1.2}p^{n-2}q^2 + \ . \ . \ .\right).$$

Then I premise that to fit this to any real curve we *cannot* (1) use the length of base $(n+1)c$, for by trial I find this is never sufficiently accurately known; (2) use the magnitude or position of the maximum ordinate of the observation curves, for the first is not accurately known, and the second is dependent on knowing the exact end of the observation curve.

Accordingly I proceed *not* by the method suggested in Prof. Edgeworth's "Law of Error and the Elimination of Chance" (*Phil. Mag.* p. 318, April 1886), but by a method of higher moments.

Reckoned from O, the distance ON to the vertical through the centre of gravity, G, of the system of rectangles is $c(1+nq)$.

I now calculate the moments of the rectangles round the vertical, OY, and find for the rth moment

$$M_r = \alpha c^r \frac{d}{dq} q \frac{d}{dq} q \frac{d}{dq} \ . \ . \ . \text{ to } r \text{ differentiations } \{q(p+q)^n\},$$

where $p + q$ is only to be put unity after differentiation, and c is supposed small. From the first four moments about OY, I find the first four moments about NG with the following results:—

$$\mu_1 = 0,$$
$$\mu_2 = npq\alpha c^2,$$
$$\mu_3 = n/q(p-q)\alpha c^3,$$
$$\mu_4 = npq\{1 + 3(n-2)qp\}\alpha c^4.$$

Now the centre of gravity of the observation curve is found at once, also its area and its first four moments by easy calculation. Thus the position of NG, α, μ_2, μ_3, and μ_4 are given quantities. Taking the values of μ_2, μ_3, μ_4, given above, and also $p+q=1$, I have four equations to determine p, q, n, and c.

Solving them, I have the following results:

p and q are roots of the *quadratic*;

$$p^2 - p + \frac{(3\mu_2^2 - \mu_4)\mu_2 + \mu_3^2}{4(3\mu_2^2 - \mu_4)\mu_2 + 6\mu_3^2} = 0;$$

$$n = \frac{2\mu_2^3}{(3\mu_2^2 - \mu_4)\mu_2 + \mu_3^2};$$

$$c = \frac{\sqrt{2(3\mu_2^2 - \mu_4)\mu_2 + 3\mu_3^2}}{\mu_2^2}.$$

As verification note that for the normal probability curve $3\mu_2^2 = \mu_4$ and $\mu_3 = 0$.

Thus we have

$$p^2 - p + \tfrac{1}{4} = 0, \text{ i.e. } p = \tfrac{1}{2}, \text{ and } q = \tfrac{1}{2},$$
$$n = \alpha, \text{ and } c = 0,$$

as it should be.

The method enables us to fit a binomial to any asymmetrical curve, the results being based on no single ordinates, but on the moments of the whole system throughout.

The importance of this solution is that it enables us to determine p and q very approximately for any system of physical, biological, or sociological measurements; *i.e.* it tells us how much greater is the tendency for a deviation to occur on one side of the mean rather than on the other. A scientific measure of this is clearly given by

$$\frac{\mu_3}{\mu_2} = (p - q)c,$$

which measures the asymmetry of the frequency curve, and tells us at the same time the difference of p and q.

University College, October 17. KARL PEARSON.

British Association Report on Thermodynamics.

As I am now drawing up a second report for the British Association, on certain researches connected with thermodynamics, may I be permitted to invite the assistance and cooperation of all specialists in that subject?

It is proposed to deal with (1) the "Boltzmann-Maxwell" law of distribution of energy in systems of colliding and non-colliding bodies; (2) the virial equation when intermolecular force is taken into account, and its application to liquids and gases. It is desirable that the report shall be completed in time for the 1894 meeting of the Association.

The compilation of reports on different branches of science is one of the most important functions carried out by the British Association, but it is essential that every paper bearing on the subject of a report should be consulted in its preparation. The labour involved in wading through the enormous mass of existing literature on any physical subject can only be appreciated by those who have undertaken such work, and there is a constant risk of overlooking important papers, which are often buried in the Transactions of some obscure foreign society. It sometimes happens, too, that such papers cannot be procured, and hence cannot be consulted, to the great detriment of the report. May I therefore hope that the authors of any investigations bearing on the subjects of my report will kindly send me reprints? Lists of papers or suggestions will also be most acceptable.

G. H. BRYAN.

Thornlea, Trumpington Road, Cambridge, October 18.

Curious Phenomenon.

I WAS on the top of a small mountain in the Dövrefjeld, near Hjerkin, in the late afternoon of August 26, the sun being 10–15° above the horizon, when I saw a remarkable phenomenon. On the opposite side to the sun was a bright disc, perhaps 5° in diameter, shown on some drifting clouds. The shadow of my head appeared in the centre of the disc, that of my body below, while outside the disc the shadow of my legs was faintly visible. The phenomenon continued on and off—that is to say, when the clouds were favourable—for nearly a quarter of an hour. The landlord of the hotel said he had never seen anything of the sort.

HUMAN AND COMPARATIVE ANATOMY AT OXFORD.

ON October 14, a distinguished company, including the Professors of Human Anatomy in Edinburgh and Cambridge, the President of the College of Surgeons of England, and many well-known medical men and teachers, attended the opening of a new institute of Human Anatomy by the Vice-Chancellor of the University of Oxford.

The occasion is one in connection with which a few words are appropriate concerning the history of anatomical studies in Oxford and the relation between the special technical study of the anatomy of man required by medical students, and the more general study of the comparative anatomy of man and animals, or animal morphology. Historically the study of natural science has had the closest connection with the profession of medicine. In the last century, zoology and botany were not pursued in the universities of Europe as branches of science to be studied for their own intrinsic value as departments of knowledge, but primarily as giving the student acquaintance with "drugs" or "materia medica." Linnæus was the first university professor who lectured on animals from the strictly zoological point of view; until his time, animals had been studied, even in the universities, chiefly in relation to their supposed medicinal virtues. Concurrently the anatomists, who had mainly confined themselves to exploring the structure of the human body and of the animals nearest to man, extended their area of study. Through John Hunter and Georges Cuvier an immense body of knowledge as to the anatomy of all kinds of animals was accumulated and systematised, to which the name Comparative Anatomy was applied—more especially by Cuvier and his followers.

In this country, and very generally elsewhere, the study of "comparative anatomy" was carried on by men like Hunter, members of the medical profession, even practitioners. In the earlier half of the present century it was usual to find in the universities of Germany, as well as of Britain, that anatomy, including the wider comparative anatomy, as well as the topography of man required for medical purposes, together with physiology and even pathological anatomy, were all taught by one professor. Thus the great Johannes Müller discharged this multiple function until his death in Berlin in 1858.

It is not therefore surprising that when the Oxford University Commissioners of 1856 revived the ancient foundation of Linacre, they charged the new professor with the teaching of both anatomy and physiology. To this large task Rolleston, the first Linacre professor, devoted himself with characteristic energy and with a breadth of view which few nowadays could command. Rolleston taught physiology, comparative anatomy, as well as that topographical anatomy of the human body which medical training demands—a pursuit which he loved to call "anthropotomy." Anthropotomy was not neglected in Rolleston's time; those students of the University who wished to pursue human dissections in Oxford found the necessary material and assistance in his department.

The more recent Commissioners (of 1880) came to the conclusion that it was desirable that a separate chair of Physiology should be founded in the University of Oxford, and accordingly instituted such a professorship from the funds of Magdalen College, whilst they altered the title and scope of the Linacre chair to "Human and Comparative Anatomy." It was to the Linacre chair thus modified that Moseley was appointed on the death of Rolleston in 1881, whilst subsequently Burdon Sanderson was appointed to the newly-created Waynflete (Magdalen) chair of Physiology.

A further division of labour now became desirable. The teaching of anthropotomy—the medical student's necessary groundwork—could not be carried on personally by the same professor who was charged with the subject-matter of Cuvier's life-work. It was a question between either assigning to the Linacre Professor a specially qualified assistant to superintend the dissecting-room of Human Anatomy, or appointing an independent lecturer in that subject. The latter course seemed to be the better, and Mr. Arthur Thomson, the senior demonstrator in the Medical School of Edinburgh University, was appointed as Lecturer in Human Anatomy in Oxford. The expressed purpose of this appointment was to relieve the Linacre professor of that part of his duties which consisted in teaching human anatomy for the specific purposes of medical education, and it was in no way proposed to remove from the professor his functions as a teacher of the anatomy of man in its morphological aspects and his duties as guardian of the anatomical and ethnological collections of the University.

On the death of Prof. Moseley, in 1891, I was appointed his successor in the Linacre chair of Human and Comparative Anatomy. The University voted funds for the building and fitting of additional laboratories for the Linacre professor (which were completed and opened without ceremony last year) at the same time that we approved the expenditure necessary for a new laboratory for Human Anatomy. At my suggestion a statute was prepared, and has received the assent of her Majesty in Council, removing the words "human and" from the title of the Linacre professor; so that the professorship in question is now the "Linacre professorship of Comparative Anatomy," whilst the duty of teaching anthropotomy or that special study of the topography of the human body which medical training requires, is definitely assigned to the "lecturer in Human Anatomy."

The consideration of human structure in relation to that of vertebrate animals—the morphology of man as of other animals—the "comparative" anatomy of man and animals—remain as heretofore the charge of the Linacre professorship. In short, the treatment of man's structure as part of the general science of morphology remains necessarily the business of the professor of Comparative Anatomy. The exposition of the geography of the human body, in which the surgeon, and to some extent the physician, must be as expert and familiar as a townsman in the pathways of the city in which he resides and does his business—is the distinctive function of the teacher of "human anatomy" in a medical school. It is for this special purpose that we have just added to the excellent laboratories and museum already arranged and used for the study of anatomy in its widest sense, a new dissecting room and adjuncts adapted to the reception and proper treatment of human bodies.

It is to be hoped that the effort now made by the University to establish technical training in anthropotomy as an independent ffshoot of the Linacre professorship may be successful. The older laboratories and museum-collections of Comparative Anatomy and Craniology, which are attached to the Linacre professorship, do not need advertisement; they have been rendered famous by the scientific discoveries and researches of those who in the past have held that office. Of the new rooms for the study of anthropotomy, we have the expectation that they will in the future, under the care of successive lecturers in Human Anatomy, add to the attractions of the University as a centre of professional training, and justify the policy which has led us to the expenditure necessary for their erection.

E. RAY LANKESTER.

CELESTIAL PHOTOGRAPHY AT THE PARIS OBSERVATORY.

A DESCRIPTION of the work that is being done in connection with the photographic star chart and catalogue is given in *La Nature* by M. A. Fraissinet. We are indebted to that journal for the accompanying illustrations and the following information referring to them.

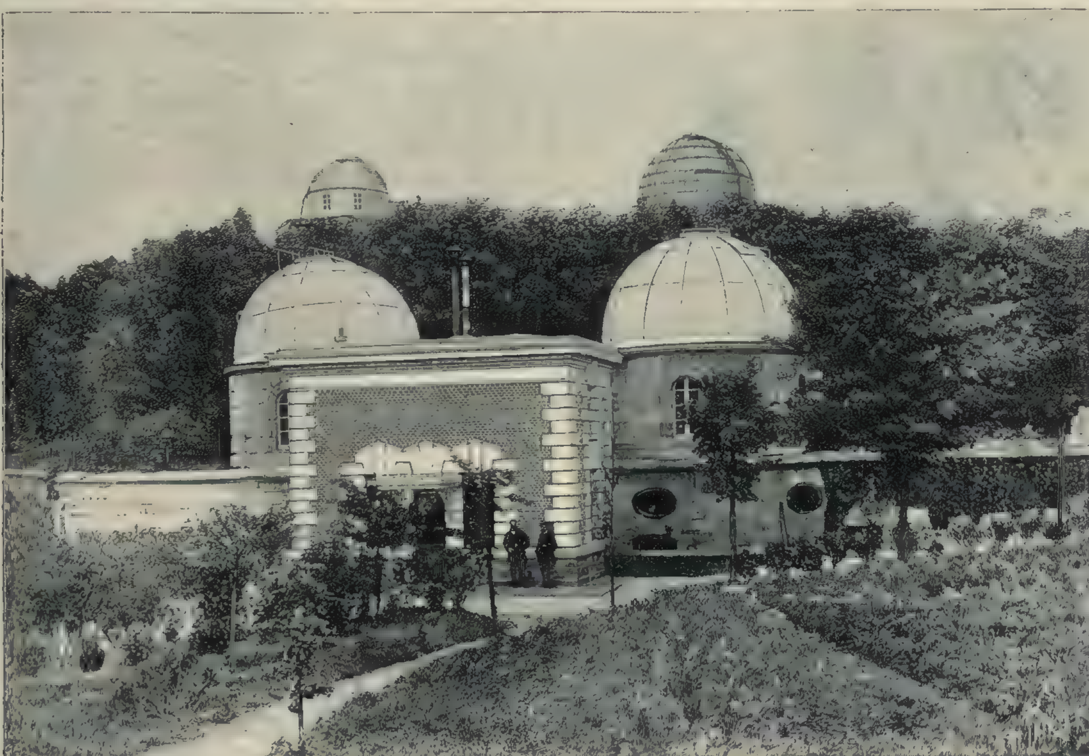

FIG. 1.—The part of the Paris Observatory devoted to the Photographic Star Chart.

A special bureau for the measurement of the stellar photographs designed for the catalogue was organised at the Paris observatory in 1892.

To accommodate the new service the building shown in Fig. 1 was erected. On the first floor of the new building a photographic laboratory has been established. The ground floor has been set apart for the service of the measurement of clichés organised by MM. Henry. This service is under the direction of Mdlle. Klumpke, who is assisted by four other ladies.

Two measuring machines were provided last year of the new kind devised by Gautier, and supplied to the French and some foreign co-operating observatories.

The instrument is illustrated by Fig. 2. It consists at the lower part of a fixed horizontal piece having two rails on which a carriage may be caused to slide by means of a screw. Under the face of the carriage inclined to the horizontal at an angle of 45° is another screw geared to a frame on which moves a circle carrying the fixed holder which receives the plate to be measured.

Each plate after it has been put in the holder can be subjected to three movements: a movement of rotation, which serves the purposes of orientation, and two rectilinear movements, one of which takes place on the horizontal and the other on the inclined plane. Each of the rectilinear movements can be roughly read off by means of the millimetre scales attached to the planes. Fractions of a scale division are determined by means of the micrometer screws. The head of each screw is divided into one hundred parts, and this is further divided into ten by estimation. Since, then, one turn of the screw corresponds to one minute of arc, it is possible to read to 0·6″ by means of the micrometer divisions.

It is hoped that in five or six years all the plates required from each observatory will have been obtained,

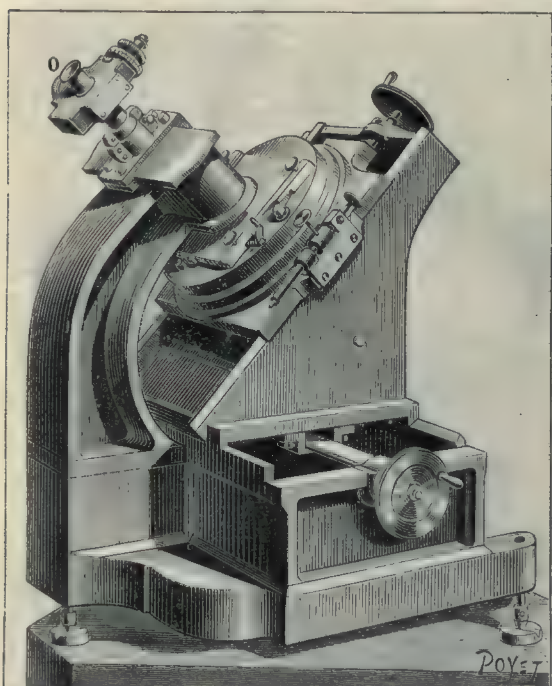

Fig. 2.—Instrument for Measuring Star Photographs. O, Observing Microscope.

but the measures can hardly be completed in less than ten years, and the computations to which they give rise will occupy about the same length of time. This rate of progress, however, cannot be regarded as slow for it must be remembered that the results will occupy forty ponderous volumes of one thousand pages, each page containing the positions of fifty stars.

When the immense labour involved is taken into consideration, one ceases to wonder that some of the co-operating observatories are unable to keep up with the measurements. It is to be hoped that lack of funds may not be allowed to prevent the obtaining of proper assistance in such cases, or to retard the publication of the results as soon as they are ready.

SMITHSONIAN INSTITUTION: HODGKINS FUND PRIZES.

In answer to inquiries, and in further explanation of statements made in the Hodgkins circular (Nature, vol. xlvii. p. 611), it may be added that *any* branch of natural science may offer a subject of discussion for the Hodgkins prizes where this subject is related to the study of the atmosphere in connection with the welfare of man.

Thus, the anthropologist may consider the history of man as affected by climate through the atmosphere; the geologist may study in this special connection the crust of the earth, whose constituents and whose form are largely modified by atmospheric influences; the botanist, the atmospheric relations of the life of the plant; the electrician, atmospheric electricity; the mathematician and physicist, problems of ærodynamics in their utilitarian application; and so on through the circle of the natural sciences, both biological and physical, of which there is perhaps not one which is necessarily excluded.

In illustration of the donor's wishes, which the Institution desires scrupulously to observe, it may be added that Mr. Hodgkins illustrated the catholicity of his plan by citing the work of the late Paul Bert in atmospheric electricity as a subject for research, which, in his own view, might be properly submitted for consideration in this relationship.

While the wide range of the subjects, which the founder's purpose makes admissible, cannot be too clearly stated, it is equally important to emphasise the fact that the prizes in the different classes can be awarded only in recognition of distinguished merit.

S. P. Langley.

NOTES.

Prof. Virchow was elected honorary president of the Berlin Medical Society on Monday.

The death is announced of Prof. Léon Lefort, vice-president of the Paris Academy of Medicine.

Prof. Schauta, of Vienna, has received the Cross of a Knight of the Order of the North Star from the King of Sweden.

A dispatch from Valparaiso announces that a volcanic eruption has occurred near Calbuco, causing great damage to that town.

We are glad to learn that Prof. von Helmholtz is recovering from the injuiries he sustained from falling down a companion ladder on board the *Saale*, while returning from his recent visit to America.

The Franklin Institute has received the sum of one thousand dollars from Mr. A. A. Boyden, to be rewarded as a premium to any resident of North America who shall determine by experiment whether all rays of light, and other physical rays, are or are not transmitted with the same velocity.

Miss Ormerod has received a report from her correspondent on crop insect pests in Norway to the effect that the Hessian fly is now for the first time recorded as occurring in Norway and doing damage to barley. Specimens of the infested straw, showing the presence of the flat brown chrysalis of the *Cecidomyia destructor*, were sent with the report.

Dr. J. W. Gregory has returned from East Africa after a very successful investigation of the geology and natural history of Mount Kenia and the neighbouring region. His observations, and the large number of geological, zoological, and botanical specimens collected during the expedition, add considerably to our knowledge of the character and capabilities of British East Africa.

With reference to the reported outbreak of cholera at Greenwich, Dr. Thorne Thorne reports that, whilst in certain important respects the materials that have been investigated suggested that cholera was in question, it now transpires that in every case examined one or more of the ordinary proofs as to this have been wanting, and Dr. Klein concludes that the outbreak is not one of true cholera.

AFTER the 1st of November the time of Central Europe, which is employed in Sweden, Germany, Austria, Hungary, Bosnia, and Servia, and is reckoned from the fifteenth degree of longitude, will be adopted upon Italian railway-systems. Railway time in Italy will therefore be exactly one hour in advance of Greenwich time, and 50 min. 39 secs. in advance of Paris mean time, the difference of time between Greenwich and Paris being 9 min. 21 secs.

THE passengers on board the North German Lloyd s.s. *Oldenburg*, which left Genoa for the East on the 23rd inst., include Dr. W. Kükenthal, Ritter Professor in the University of Jena, who proceeds, under the auspices of the Senckenberg Naturalists' Society, on a twelve months' zoological expedition to the Moluccas. After a short sojourn in Java, he will make Ternate his headquarters, exploring the surrounding islands, and especially the island of Halmahera. We are informed that Prof. Kükenthal was the elected one of fifty zoologists who sought the leadership of the expedition. The energy and endurance which he displayed in his recent investigations in the Arctic Seas led to the accumulation of rich material, and they justify an anticipation of good results from the present, less tropical, journey.

THE exhibition arranged by the Deutsche Mathematiker-Vereinigung at Munich, of models, drawings, apparatus, and instruments used in pure and applied mathematics, was closed on October 5. From a circular that has been issued by the Association we learn that the exhibition was in every respect successful. Owing to the support given by the Royal Bavarian Government and the Ministry of the Interior, it was possible to considerably extend the plans originally proposed. The success of the undertaking was largely due to the kindness of the many public bodies and private individuals who lent apparatus, &c., and have participated in the work, often at a pecuniary sacrifice. The committee of the Association desire to express their thanks to exhibitors and others who have supported them during the last two years.

THE following gentlemen have been nominated for election on the council of the London Mathematical Society for the session 1893-4:—Mr. A. B. Kempe, F.R.S. (President); Messrs. A. B. Basset, F.R.S., E. B. Elliott, F.R.S., A. G. Greenhill, F.R.S. (Vice-Presidents); Dr. J. Larmor, F.R.S. (Treasurer); Messrs. M. Jenkins and R. Tucker (Hon. Secs.). Other members—Dr. Forsyth, F.R.S., Dr. Glaisher, F.R.S., Dr. Hill, Dr. Hobson, F.R.S., Mr. Love, Major Macmahon, F.R.S., Mr. J. J. Walker, F.R.S. The new nominees are Lt.-Col. J. R. Campbell and Lt.-Col. A. J. C. Cunningham, R.E., in the place of Messrs. H. F. Baker and J. Hammond, who retire. The annual general meeting (November 9) will be made special for the consideration of the following resolution, which will be moved by the council: "That the London Mathematical Society be incorporated as a Limited Liability Company under Section 23 of the Companies Act, 1867; and that the Council be empowered to take the necessary steps to carry this resolution into effect." The presentation of the De Morgan medal, awarded by the council in June last, will be made at the same meeting, to Prof. Felix Klein, the medallist, who expects to be present to receive it in person.

WE have received the first part of the second half of vol. iii. of Cohn's *Kryptogamen-Flora von Schlesien*, devoted to the fungi, under the editorship of Dr. J. Schrœter. The present part commences the description of the Ascomycetes, and is occupied by a portion only of the first sub-order, the Discomycetes.

THE second part of vol. vi. of the *Journal* of the College of Science of the Imperial University of Japan is entirely occupied by an elaborate paper, by Prof. Sadahisa Matsuda, on the anatomy of the Magnoliaceæ. It is illustrated by four plates exhibiting the excellence of work to which we are now accustomed in the products of the Japanese press.

DR. R. A. PHILIPPI contributes to the *Verhandlungen* of the German Scientific Society of Santiago in Chile two interesting papers on the "Fauna and Flora of Chile and Argentinia." With regard to the flora he points out that, notwithstanding the wide difference between those of Chile and of Europe, the number of identical species is greater than Europe has in common with South Africa or Australia; while both the flora and fauna of Chile differ in a very remarkable way from those of Argentinia. Dr. Philippi argues from these facts that the mountain range of the Cordilleras must have been formed before the development of the fauna and flora of these countries.

AMONG other excerpts from the Transactions of the Academy of Science of St. Louis, vol. vi., that have recently been received, the following are of interest:—"The Opening of the Buds of Some Woody Plants," by Mr. A. S. Hitchcock. This paper records observations made during the spring of 1892. In "Flowers and Insects—Labiatæ" Mr. Charles Robertson gives an account of the pollinators of various Labiates. Of the twenty-three species described, nine have long-tongued bees as their principal visitors, and eight show special adaptation to bees in general. No species was found to be adapted to the lower hymenoptera, though ten species were visited by them. Diptera occurred as visitors of nineteen species, and butterflies on all but five species. The ruby-throated humming-bird only visited *Monarda, Bradburniana*, and *M. fistulosa*, and beetles were found only on the six least specialised flowers investigated. Mr. J. Christian Bay has prepared the materials for a monograph on Inuline, in the form of a list of papers on the subject, published up to the end of 1890.

DR. EDMUND NAUMANN, the well-known writer on Japan Geology, has just published an interesting paper in *Petermanns Mittheilungen* (Ergänzungsheft, No. 108), under the title of "Neue Beiträge zur Geologie und Geographie Japans." Three coloured plates are given—plate i. the crater of Shiranesan and views of Bandai, two volcanoes active within recent years; plate ii. a stereographic representation of the geology of Japan (scale (1 : 5,000,000); plate iii. the general contours of the country (scale 1 : 2,600,000).

JAPAN is possibly one of the best illustrations of the value of geological knowledge in throwing light and colour on the geographical features of a country. Dr. Naumann, in his account of the geological structure of the great mountain chain, emphasises the presence of a crystalline core throughout the whole length of the islands, and against it the sedimentary deposits may be said to have a zonal distribution. He proves that while there was prepalæozoic folding in these crystalline schists and gneisses, the main period of mountain-movement and the upheaval of the greater portion of Japan took place in early Mesozoic times. The intrusions of the enormous granitic masses are probably of late Mesozoic age, and since that time there have been several periods of volcanic activity, constant recurrences taking place along ancient lines of weakness. The result of the particular processes of mountain-making in Japan on the present configuration of its surface, and the correlation of the rocks with the various types of landscape, are then briefly described.

THE "Fossa magna" is an apt name given some years ago by Dr. Naumann to that curious well-marked depression between the north and south wings of the main island—a de pression bordered by the highest summits in Japan, and occupied by a girdle of volcanoes. Ed. Suess ("Antlitz d. Erde," bd. ii. p. 225) and the Japanese geologist, Harada, are of opinion that the mountains in the north and south wings belong to two independent chains which during the period of upheaval had been pushed against one another at this "fossa magna," and they compare the case of Hindu Kush and the Himalayas. Dr. Naumann still adheres to the view he had previously advanced, namely, that the mountains of the north and south wings form one chain, which after its upheaval was broken by a transverse fault along the "fossa magna," the transverse fault being of later date than the main longitudinal fault on the west or inner side of the islands and cutting through it. The eruptive activity and frequent subsidences within the "fossa" have merely taken advantage of this important tektonic break.

THE Report on the Botanic Gardens at Georgetown, British Guiana, for the year 1891–92, contains some interesting information on the meteorology of that colony for the year 1891. The rainfall was much above the average, though not so much so as in the two previous years. For the nine years ending 1888 the average fall was 80·5 inches, but for the three years ending 1891 the average fall has been 119·6 inches; the returns from various stations show that there is a gradual increase in the rainfall from the south to the north of the colony. The number of days on which the sun shone was 351, leaving only 14 days of unbroken cloudiness; the mean daily sunshine for the year was 7h. 13m. The maximum day temperature in the shade ranged from 84° in February to 90° in September and October. The minimum night temperature ranged from 71° to 74°, and the solar radiation from 148° to 157°.

A CAREFUL study of the vapour pressures of aqueous solutions has been carried out by C. Dieterici, of Breslau, who has communicated his results to *Wiedemann's Annalen*. The determinations were made for 0° C. by means of an apparatus designed for the appreciation of very feeble pressures. The gauge used was an aneroid box with a German silver disc, which has the advantage of yielding to a great extent without elastic fatigue. The motions of the centre of the disc were transferred to a mirror suspended in jewelled bearings by means of a light watchmaker's arbor, the connection being made by a cocoon thread, and the mirror being gently held in position by a small spiral spring. Deflections were measured by reflected scale and telescope. The gauge was fitted to a tube which could be filled with the vapour of the solution surrounded by melting ice, or could be exhausted at pleasure. The gauge and tube were enclosed in another air-tight space which could be filled with pure water vapour at 0° C. or exhausted. The pressure of the water vapour produced a deflection of 170 scale divisions, equivalent to 2·31 mm. of mercury. The author discusses at length the bearing of his results upon Van't Hoff's dissociation theory, and upon the kinetic theory of gases. The curves exhibiting the relation between degree of concentration and the corresponding vapour pressure have the common characteristic that with the concentration increasing from an infinitely dilute solution to about 26 in multiples of the normal solution, they commence at approximately the same angle, then fall with a steep incline, and finally tend to become parallel to the axis of abscissæ. At about 26 the curve of sulphuric acid cuts this axis, showing that the action between the acid and the water counterbalances the osmotic pressure necessary for evaporation. The other bodies investigated were glycerine, phosphoric acid, and the hydrates of potassium and sodium, enumerated in the order of decreasing vapour pressures.

THE current number of the *Philosophical Magazine* contains an account of the most recent determinations of the refractive indices of liquid nitrogen and air, carried out by Profs. Liveing and Dewar. Owing to the bubbles constantly rising from liquid nitrogen, the prism method could not be made to give accurate results. The refractive index was therefore determined by finding the angle of total reflection. The liquid nitrogen, or air, was enclosed in a cylindrical vessel containing two vertical plane-parallel plates of glass with a film of air between them. The light from an electric discharge or a monochromatic flame was sent through a slit into the vessel, a suitable portion being cut off by black paper screens, and an image of the slit was thrown upon the slit of a spectroscope by the glass vessel itself. The vertical plates were turned round a vertical axis till the extinction of the image indicated that the angle of total reflection had been reached. The refractive index thus obtained for sodium light was 1·226 in the case of liquid oxygen (the prism method gave 1·2236), 1·2062 for liquid air, and 1·2053 for liquid nitrogen at −190°, and of density 0·89. The nitrogen probably contained 5 per cent. of oxygen. The refraction constant of nitrogen is therefore 0·225 as determined from the liquefied substance. Mascart gives 0 237 for the constant as determined from gaseous nitrogen. The two results are in as fair an agreement as could be expected, considering the difficulties surrounding the measurements.

WIEDEMANN'S *Annalen de Physique et de Chemie* for October contains a paper, by R. J. Holland, on electrical conductivity of copper chloride solution. The solution, whose resistance was to be measured, was enclosed in a dumb-bell shaped glass vessel about 10 c.m. long, the electrodes, which had a surface of 2¼ sq. c.m., being fixed at the ends. In order to determine the mean section of the tube between the electrodes, it was filled with a solution of sodium chloride and the resistance measured, then using Kohlrausch's results for the resistance of the salt solution the mean section was calculated. The resistance was measured by means of a Wheatstone's bridge, with an alternating current and telephone. All the strengths of copper chloride solution examined show a regular, though slight, increase of conductivity at high temperature, this increase being different for solutions of different degrees of concentration. The maximum conductivity was obtained with a solution containing about 18 per cent. of the dried salt. The temperature coefficient varies with the degree of concentration, and attains a maximum value for a temperature of about 40° C. When the difference in concentration is taken into account, the results obtained agree very well with those obtained by Trötsch and Wiedemann, though they do not show so satisfactory an agreement with those obtained by Isaachsen.

L'Elettricista for October contains a paper by Dr. Monti, in which he gives the results of the experiments he has undertaken in order, if possible, to account for the fact that the values obtained by Macfarlane in 1877 for the difference of potential required to pierce a plate of paraffin were very much smaller than those obtained by Steinmetz and himself. Macfarlane found that the difference of potential required to pierce a plate of paraffin 3 mm. thick was 39,000 volts, while Dr. Monti finds that to cause a discharge to pass between two knobs 5 mm. in diameter through a layer of paraffin 1 mm. thick it requires a difference of potential of 155,000 volts. The author employed paraffin which melted at 54·76° C. The terminals were brass balls which were fixed within a glass tube about 10 c.m. long. Their distance apart having been measured by means of a microscope, the paraffin was melted and allowed to cool in a partial vacuum. It was then again melted and allowed to solidify under the ordinary pressure. By this means the formation of air bubbles within the paraffin was avoided, and it is to the presence of such air bubbles in the slab of paraffin employed by Macfarlane that Dr. Monti attributes the difference in the values obtained.

AN electrical method of fog-signalling, which has great possibilities before it, has been invented by an electrician in the employ of the Great Northern Railway Company. A wire is laid by means of a pipe from the signal-box to the various signals, at which points brushes composed of copper wire project some four or five inches above the side of the rail nearest the signal. To the foot-plate of the engine a similar brush is fixed, connecting with an indicator and bell on the engine. If the signal be at danger the two brushes coming in contact has the effect of ringing the bell, and indicating to the driver by means of a miniature signal fixed on his engine that the line is not clear. The arrangement can be switched off in fine weather. The process, which is in working order at Wood Green, has proved so satisfactory that the company have decided to fit up the suburban lines, and eventually the whole of their system.

THE report of the meeting of the *Société Helvétique des Sciences Naturelles*, held at Basle in September 1892, has just been published.

Natur und Haus, edited by Dr. L. Staby and Herr Hesdörffer, begins its second year with a number full of articles on a variety of scientific topics. The journal must help to popularise science in the Fatherland, for its contents—both text and illustration—are excellent.

THE second year's meetings of the University Extension Philosophical Society will commence on Friday, October 27, at 8 p.m., when Mr. Bernard Bosanquet will give an address on "Atomism in Psychology," at Whitelands College, Chelsea. Among other gentlemen who will read papers during the present year are Prof. Sully, Mr. G. F. Stont, Mr. C. S. Loch, and Mr. P. H. Wicksteed.

THE trustees of the Australian Museum have issued their thirty-ninth annual report. We are sorry to notice that there has been a slight falling off in the attendance of visitors during the year 1892. The number of visitors was 130,701, being fewer by 2144 than in the previous year. The average week-day attendance was 265, and that for Sundays 712.

THE following lectures will be delivered at the Royal Victoria Hall during November:—November 7, Mr. Francis Bond, on "Norway and the Norwegians"; November 14, Prof. H. G. Seeley, F.R.S., on "Skulls"; November 21, Mr. James Swinburne, on "The Mechanics of Street Toys"; November 28, Mr. Douglas Carnegie, on "The Philosopher's Stone, or the Royal Road to Health and Wealth."

A NEW and revised edition of "Our Reptiles and Batrachians," by Dr. M. C. Cooke, has been published by Messrs. W. H. Allen and Co. As the author remarked in the preface of the original edition, he aimed at producing "a popular volume on a rather unpopular subject," and not a work for the man of science. The fact that a new edition has been called for shows that the general public appreciate tales of snake-stones and the incarceration of frogs in blocks of granite; of the "toad's envenomed juice," and incombustible salamanders. However, in the reading of these accounts something is learned concerning the habits and characters of the lizards, snakes, newts, toads, frogs, and tortoises indigenous to Great Britain; so instruction is happily combined with amusement.

THE "Zoological Record for 1892," edited by Mr. David Sharp, F.R.S., and being the twenty-ninth volume of zoological literature, has just been published. The scope of the Record has been greatly enlarged, and an index of special subjects has been included in each department, in addition to the list of titles and the taxonomical arrangement according to genera. It has not been possible, however, to make a complete epitome of palæontological literature; indeed, Mr. Sharp thinks that palæontologists should undertake the compilation of a separate record. We are inclined to agree with this. Everyone knows that an incomplete record is of very little use; for valuable time may be wasted in searching through it for references which it does not contain. But if every branch of science had a publication which did for it what the "Zoological Record" does for zoology, scientific papers would be in a fair way of organisation.

SOME years ago Prof. Frank Clowes communicated to the Royal Society and to the Aberdeen meeting of the British Association the fact that there occurred in the neighbourhood of Nottingham a large area of sandstone, in which the cementing material was wholly crystalline barium sulphate. The subject was mentioned again in the Geological Section at the recent Nottingham meeting of the British Association, and several geologists gave instances of similar sandstone occurring in other parts of England. Prof. Clowes writes that he would be glad to learn of the occurrence of such sandstone in any locality, and to receive specimens for examination and chemical analysis.

WE have received part 4, vol. v. of the Transactions of the Norfolk and Norwich Naturalists' Society, and are glad to find that both financially and numerically the society is in a satisfactory condition. Of the 250 members many are non-resident in the county, and it is probably owing to their help that for a small subscription the society is able to issue a goodly publication consisting of more than 190 pages. The address of the president, Mr. H. B. Woodward, of the Geological Survey, deals mainly with the geology of the county, which presents many very interesting features, and he also contributes a memoir (with portrait) of the late Caleb B. Rose, one of the fathers of Norfolk geology. These memoirs of local naturalists of note form a marked feature in the society's publication, as also do the lists of the fauna and flora of the county, the twelfth of which, namely the Coleoptera, by Mr. Jas. Edwards, in which 1728 species are enumerated, is included in the present number. Amongst the other contributions are a very interesting paper on tortoises in domestication, by Sir Peter Eade, containing measurements and weights of two tortoises, taken annually since the year 1886; notes on the occurrence of the Siberian pectoral sandpiper and Sowerby's whale in Norfolk, on the Lapland bunting, the Holkham shooting parties at the commencement of the present century, on Norfolk slugs, and other matters of local and general interest.

IN these Notes on August 24, reference was made to some recent modifications in the method for staining the cilia of micro-organisms. Strauss mentions in the *Bulletin Médicale*, 1892, No. 51, that he has succeeded in colouring the cilia of the cholera spirillum, the spirillum Metschnikowi, and Finkler Prior's spirillum in a *living* condition. For this purpose broth cultures, from 1–3 days old, are employed, one needle-loop of which is placed on a microscopic slip and carefully mixed with a needle-loop of Ziehl's fuchsin solution diluted with water (1 : 3–4). A cover glass is then superposed, and the preparation examined under the microscope as rapidly as possible. The above-mentioned organisms become intensely red in colour, and many retain their motility for a short time, and at one of the pores may be seen the extremely thin corkscrew-shaped or wavy cilium-tinted pale red containing more highly coloured granules, which are disposed in longitudinal series in its interior. When the organism is no longer in a living condition, the cilia may still be seen although less distinctly, whilst numerous isolated and detached cilia may be seen moving with great activity in the fluid. Strauss has not so far been successful in exhibiting by this method the cilia of other organisms in a living condition.

It is usual in cases of thrush to recommend the use of alkaline substances in order to counteract the acidity of the mouth, which is generally supposed to favour the growth of the thrush fungus. Some recent researches of Marantonio ("Contributo alla biologia del fungo del Mughetto" Istituto d'Igiene di Roma, vol. xii. 1893, p. 199) show, however, that this fungus grows abundantly in strongly alkaline as well as in acid media. Experiments were made to ascertain what substances exerted a bactericidal action on this organism, special attention being given to those usually prescribed in the treatment of thrush. It was found that many of these were quite ineffective, on the other hand salicylic acid, amongst others, was highly efficacious; these laboratory experiments were, moreover, confirmed in actual practice, for extremely encouraging results were obtained when this substance was tried in some cases of thrush in children in one of the hospitals in Rome. In some hospitals it appears that thrush is endemic, and Marantonio was able to isolate out the organism of this disease from the dust in the interstices of the flooring of a children's ward; considering that the fungus can successfully resist the effects of desiccation over four and a half months, this fact is not surprising. The behaviour of this organism when exposed to sunshine was also investigated. Portions of vigorous agar-cultures were spread in thin layers on pieces of white cardboard, which were placed in glass boxes, some being preserved in the dark, whilst others were insolated for various lengths of time. It was found that thirteen hours' exposure to direct sunshine retarded the development of the fungus, whilst when prolonged for seventeen hours it was completely destroyed. The great mortality which prevails amongst children suffering from thrush should render these elaborate and carefully-conducted experiments of especial interest and importance.

Carbide of boron has been isolated by Dr. Mühlhäuser, of the University of Chicago, and is described by him in the current publication of the *Zeitschrift für Anorganische Chemie*. It proves to be an extremely stable substance, being capable of successfully resisting the action of almost all the usual solvents and reagents. Its composition has been ascertained by taking advantage of the fact that chromate of lead is capable of oxidising it at the usual temperature of a combustion furnace. The analytical data indicate the simple empirical formula BC, but its constitution is assumed to correspond to double that formula, namely B_2C_2 or $\begin{array}{c} C \equiv B \\ | \quad\ \ | \\ C \equiv B \end{array}$. Boron carbide was prepared by heating boric anhydride with the hard variety of carbon employed for making the terminals of electric arc lamps. The reaction proceeds in accordance with the equation: $B_2O_3 + 5C = B_2C_2 + 3CO$. Five parts of borax were dissolved in twenty parts of water, one part of sulphuric acid was added, and the solution allowed to cool. The crystals of boric acid which were formed during the cooling were separated by filtration, washed with water, dried, fused, and finally heated to low redness, by which they were dehydrated, and boric anhydride produced. The powdered boric anhydride was then mixed with the powdered electrode carbon, in the proportion of five parts of the former to eight parts of the latter, and the mixture disposed upon a suitable carbon support between the terminals of a powerful arc lamp. Upon the generation of the arc by means of a current of 350 ampères action almost immediately commenced, the mixture of boric anhydride and carbon fusing and evolving a considerable amount of gas with effervescence. The operation is concluded when the effervescence ceases, when the current should be switched off and the product allowed to cool. Carbide of boron is thus produced in the form of black graphitoidal spherules, frequently aggregated so as to resemble the shape of a bunch of grapes. The spherules possess a bright metallic lustre. They may be freed from traces of the ingredients of the mixture used in their preparation by heating for a few hours in a platinum crucible, then powdering, and repeatedly treating the powder with hydrochloric acid, water, a mixture of hydrofluoric and sulphuric acids, and finally once more with distilled water. The powder thus prepared yields numbers on combustion with chromate of lead which agree closely with the formula above given. Carbide of boron closely resembles graphite in outward appearance; it blackens the fingers in a similar manner, and the coating thus transferred possesses the same bright metallic lustre and greasy feel. Examined under the microscope it appears bluish black and transparent, and reflects light with chromatic effects. When heated to a high temperature the powder cakes together, forming a soft mass, which is readily malleable and capable of being rolled. At a very high temperature it completely fuses to a liquid much resembling a molten metal. It burns only with great difficulty in oxygen, but is combustible, as above stated, with chromate of lead. It is insoluble in all the ordinary solvents, but fused caustic or carbonated alkalies attack it with formation of borate of the alkali and liberation of carbon.

Notes from the Marine Biological Station, Plymouth.—Last week's captures include the Mollusca *Lima Loscombii* and *Pholadidea papyracea*, and the Schizopoda *Leptomysis gracilis* and a number of *Erythrops elegans*. The floating fauna is unusually rich in Diatoms and Dinoflagellates, and a few Radiolaria are still to be seen. The larvæ of *Polynoë*, *Chætopterus* and *Terebella* are fairly numerous, and *Cyphonautes* and larval Lamellibranchs are plentiful. On the other hand the larvæ of Decapoda (esp. of Brachyura) are scarce, and a few Ophiuria *Plutei* are the only representatives of the Echinoderma. The more oceanic forms (*Muggiæa*, *Podon* and *Evadne*, &c.) have of late become increasingly scarce. The Hydroid *Aglaophenia tubulifera* is now breeding, and a few *Erythrops elegans* contain late embryoes in their brood-pouches.

The additions to the Zoological Society's Gardens during the past week include a Wanderoo Monkey (*Macacus silenus*, ♀) from Cochin, presented by Capt. Morgan; two Macaque Monkeys (*Macacus cynomolgus*, ♂ ♀) from India, presented respectively by Mr. John Cook and Mr. Stanley Sinclair; a Chacma Baboon (*Cynocephalus porcarius*, ♀), two Common Quails (*Coturnix communis*) from South Africa, presented by Capt. F. Baker; two Manatees (*Manatus america*, ♀ *et juv.*) from Manatee Bay, Jamaica, presented by Sir Henry A. Blake, K.C.M.G.; a Black-headed Lemur (*Lemur brunneus*, ♀) from Madagascar, presented by Miss Hoare; a Rufous Rat Kangaroo (*Hypsiprymnus rufescens*) from Australia, presented by Kenneth Crawley, Esq., R.N.; a Kite (*Milvus ictinus*) from the Canary Islands, presented by Mr. E. G. Meade-Waldo, F.Z.S.; two Purple Porphyrios (*Porphyrio cæruleus*) South-east European, presented by Mr. Joseph S. Whitaker, F.Z.S.; a Turtle Dove (*Turtur communis*) British, presented by Miss Alice L. West; a Kinkajou (*Cercoleptes caudivolvulus*), a King Vulture (*Gypagus papa juv.*), a Common Boa (*Boa constrictor*) from South America, two Ospreys (*Pandion haliætus*) from Hayti, W.I.; two Rufous-necked Weaver Birds (*Hyphantornis textor*) from South Africa; a Dunlin (*Tringa alpinus*) British, purchased; a Burchell's Zebra (*Equus burchelli*, ♀), a Wapiti Deer (*Cervus canadensis*, ♀) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

A New Comet.—*Edinburgh Circular* (No. 40, dated October 19) informs us of the discovery of a comet by Mr. W. R. Brooks, of Geneva, N.Y., at 15h. 52m. local time, its place then being R.A. 12h. 21m. N. declination 12° 55′. The comet has also been observed at Hamburg, October 17, 17h. 5·8m. Hamburg mean time. R.A. 12h. 22m. 42·9s. Declination + 13° 25′ 24″. It has a tail, and is about as bright as a star of the ninth magnitude.

DETERMINATION OF GEOGRAPHICAL LONGITUDE.—In part 15 (August 1) of the *Zeitschrift für Vermessungswesen*, Herr C. Runge, of the Technical Hochschule, Hannover, gives a very interesting account of his results in determining geographical longitude with an ordinary camera. The negative from which the results were obtained, was taken on June 17, the camera being pointed to the new moon. Eight exposures were made one after the other, with intervals of about two minutes. Without moving the camera, and after an interval of about thirty minutes, another series of pictures was taken (on the same plate), the objects this time being some stars in Leo, which were allowed to record their trails on the plate for the period of about an hour and a quarter with regular intermittent breaks of five seconds. The times of exposure were noted with an ordinary watch, and the measuring of the plates made with an accurate micrometer. Dealing here only with the accuracy of the method, we may say that the declination of the moon can be determined to 20″, and in some cases with greater accuracy; in the example given the differences between the measured and calculated values were + 11″, − 19″, + 15″, − 6′. In the measuring of the moon-distance Herr Runge says that although this was the first trial, and the star-images were not all that could be desired, yet the accuracy was surprising, and can perhaps be still increased, even without the help of any "mechanische Hülpmittel." Since the above example was made he has obtained the geographical latitude and local time by this photographic means, and with excellent results. The instrument employed consisted of a simple camera with a so-called "gruppenantiplanet" objective, by Steinheil in München, with a focal length of 24 cm. The stop used for the above plate had a diameter of 17 mm.

ASTRONOMY AND ASTRO-PHYSICS AT CHICAGO.—A few of the many papers on astronomy which were read at the series of meetings that commenced at Chicago on August 22 appear in this month's *Astronomy and Astro-Physics*, and as they are too long for individual description, we give simply the titles of the papers and their authors: "Great Telescopes of the Future," by Alvan G. Clark. This deals with the subject completely from the object-glass point of view.—"A Field for Woman's Work in Astronomy," by Mrs. M. Fleming; "Engineering Problems in the Construction of Large Refracting Telescopes," by Worcester R. Warner. This is accompanied by a photograph taken by Mr. Burnham of the 40-inch Yerkes instrument, as exhibited at the Columbian Exposition.—"The Two Magnetic Fields surrounding the Sun," by Prof. Frank H. Bigelow; "The Constitution of the Stars," by Prof. Edward C. Pickering. This paper concludes as follows: "With few exceptions all the stars may be arranged in a sequence beginning with the planetary nebulæ, passing through the bright line stars to the Orion stars, thence to the first type stars, and by insensible changes to the second and third type stars"; "Concerning the Nature of Nova Aurigæ's Spectrum," by Prof. W. W. Campbell; "Preliminary Note on the Corona of April 16, 1893," by Prof. J. M. Schæberle, being a discussion of the facts gathered from the numerous photographs taken; "The Wavelengths of the Two Brightest Lines in the Spectrum of the Nebulæ," by Prof. James E. Keeler; and lastly, "Contributions on the Subject of Solar Physics," by Prof. E. R. von Oppolzer.

A NEW ASTRONOMICAL OBSERVATORY AT MANILA.—Manila already possesses a Government meteorological and seismographic observatory, and an important astronomical observatory will soon be established there. The chief instruments will be a novel photographic meridian instrument and a large Merz refractor (19·2 inches), the latter being provided with a photographic correcting lens. Father Algue seems to be taking the work in hand, and he proposes to institute a series of latitude observations in connection with a similar series to be carried on at the Georgetown Observatory, for the determination of the variation of latitude. The instrument at Manila will consist, according to *Astronomy and Astro-Physics* for October, of two telescopes in the same tube; or at least there will be two object glasses, one at each end of the tube, their foci coinciding. These will be of the same diameter, 6 inches, and focus 3 feet, the tube being equal to the sum of the focal lengths of the object-glasses. The photographic plate is placed in the focus of the two objectives, *i.e.* in the centre of the tube. The method adopted is that of Talcott, and during the observation of both stars the instrument is not moved. The upper objective throws the image of the first star on the upper side of the sensitive film, while by the help of a basin of mercury below, and the lower objective, the trail of the second star is recorded on the under side of the same film. Besides visual work the Merz refractor will be used for photographic observations of double stars, spectrographic work, photographic parallax, &c.

THE VISIBILITY OF VENUS TO THE NAKED EYE.—Principal A. Cameron, at Yarmouth, Nova Scotia, and M. Bruguiere, at Marseilles, have made a series of observations with a view of determining for how long a period the planet Venus can be seen in the day time without optical aid (*Trans. Nova Scotia Institute of Science*, vol. i. part 2. 2nd series). Beginning with the superior conjunction of February 18, 1890, Mr. Cameron saw Venus with his naked eye 26½ days after that date, and M. Bruguiere, in the same latitude, detected the planet 4½ days before the inferior conjunction of December 4, 1890; so that altogether she was visible to the unaided eye during 259 days. The elongation of the planet when first picked up by Mr. Cameron was 6¾°, and when M. Bruguiere saw her last in November, 1890, the elongation was nearly 9°, but the brilliancy was only 6½ per cent. of the mean greatest brilliancy.

MEYER'S CONVERSATIONAL LEXICON.—The popularity of this series of volumes can only be accounted for by the very judicious way in which the publishers have dealt with every branch of science, treating it fully, accurately, and in such language that it can be understood by the most general reader. Under the heading "Astronomy" is given an excellent and concise account of the early history and development of the science. This lexicon has reached its fifth edition.

GEOGRAPHICAL NOTES.

A CABLE has recently been laid between the seaport of Bundaberg, in Queensland, and New Caledonia. This line of 910 miles, although not very important in itself, is of some interest as possibly the commencement of a great Pacific cable which may ultimately unite Australia and Canada. Should this scheme be carried into effect the probable route of the cable would be from New Caledonia to Fiji, thence to Samoa, and by Honolulu and the Fanning islands to Vancouver.

THE last number of the *Bulletin* of the Paris Geographical Society publishes the list of awards of the society's medals, the bestowal of which was noticed in this column (vol. xlviii. p. 40), together with the reports of the awards, which were too lengthy to be read at the meeting in April. A notable fact connected with these prizes is the custom of recognising the value of original maps and books of geographical research, historical or critical, as well as the work of explorers.

AN amusing instance of the danger of commenting on geographical news without referring to a full report occurs in the last number of the *Revue Française*, a journal which is valued for its full and usually accurate record of recent and projected travels. In mentioning the fact of the discovery of Active Strait, near Erebus and Terror Gulf, by the Dundee sealers this spring, the editor adds parenthetically, "volcanoes of Victoria Land to the south of New Zealand"—a pardonable mistake, as the names of Ross's ships were perhaps too freely scattered over the Antarctic regions. But in this instance it happens, somewhat oddly, Erebus and Terror Gulf is in land named after a French and not a British monarch, being in Terre Louis Phillippe, south of the Falkland Islands.

THE full programme of the Royal Geographical Society's Evening Meetings for the Session 1893–94 has been published. In addition to the subjects intimated in this column last week, we note that papers are expected by Prof. Lapworth, F.R.S., on the ups and downs of the earth's surface; by Dr. J. W. Gregory, on his expedition to Mount Kenia; Mr. R. D. Oldham, of the Indian Geological Survey, on the geographical development of India; Mr. K. Grossmann, on a journey in Iceland; Mr. T. J. Alldridge, on journeys in the interior of Sierra Leone; Dr. H. R. Mill, on the survey of the English lakes; Mr. H. Warington Smyth, on journeys on the Upper

Mekong; Mr. W. H. Cozens-Hardy, on surveys and research in Montenegro; and Mr. E. J. L. Berkeley, on British East Africa. It is also hoped that the Prince of Monaco, Sir Archibald Geikie, and Mr. J. Y. Buchanan may contribute papers. If Mr. and Mrs. Bent return in time from their projected exploring journey in Hadramant, an account of their work will be looked forward to before the close of the session.

A NUMBER of the *Journal* of the Manchester Geographical Society just issued (January to June, 1893) contains a paper on the Yoruba country, Abeokuta, and Lagos, by the Rev. J. T. F. Halligey, which gives some vivid descriptions of native life and n.anners.

DR. GERHARD SCHOTT'S physical observations on a voyage in a sailing ship from Hamburg to the China coast and back are published as an Ergänzungsheft of *Petermanns Mitteilungen*. In the discussion of his work Dr. Schott takes account of previous researches on the parts of the ocean he traversed, and his paper is an interesting addition to our knowledge of oceanography. The memoir is divided into two parts: hydrography, including a discussion of surface temperature as affected by diurnal range, rainfall, and wind, the specific gravity of surface water, surface currents and drifts, and observations on waves; and meteorology, dealing with the instruments employed, the record of air-temperature, humidity, and cloudiness. The memoir is, of course, well illustrated by maps and diagrams.

THE THICKNESS AND ELECTRICAL CONDUCTIVITY OF THIN LIQUID FILMS.

IN August, 1883, an article was published in NATURE (vol. xxviii. p. 389), signed by Prof. Rücker and myself, giving an account up to date of our researches on liquid films. Since that time our work has from time to time as opportunity offered been continued and further results have been obtained, a brief account summarise the results to which attention was drawn in 1883. of which I now propose to give. It may be useful first to briefly

A cylindrical soap film when allowed to thin under the action of gravity shows in succession the tints of the various orders of Newton's Colours, and finally becomes black. The thickness of any part of the film may be determined (supposing the refractive index to be known) from the colour it exhibits when light is reflected from it at a definite angle. The mean thickness of a horizontal ring of the cylindrical film may also be determined by measuring the electrical resistance of the ring, and by assuming the specific conductivity of the film to be the same as that of the liquid in mass. In the case of a liquid consisting of a mixture of soap solution and glycerine with a little potassium nitrate added to increase the conductivity, we proved by comparing the thickness of a film obtained by the optical method with the thickness deduced from its electrical resistance, that down to a thickness of 374 $\mu\mu$ (micromillimetres)—corresponding to colours of the second order of Newton's scale—the specific conductivity of the liquid remains unaltered. When the film becomes thinner than 374$\mu\mu$, and exhibits the colours of the first order, estimates of its thickness derived from colour observations are less trustworthy, and when these colours are replaced by black, we only know from the colour that the thickness of the film has less than a certain maximum value. Assuming, however, the specific resistance to be unchanged when the film became black we showed that the thickness of such a black film does not differ much from 12$\mu\mu$.

Experiments were then carried out by the electrical method on a solution of oleate of soda (hard soap) containing 3 per cent. of KNO_3 but no glycerine. Black films made of this solution were found to have a mean thickness of 11·7$\mu\mu$, showing that the thickness of the black is practically the same whether the solution does or does not contain glycerine. As this result, however, depends upon the validity of the assumption that the specific resistance of a black film is the same as that of a large quantity of the liquid, it was desirable if possible to measure the thickness in question by a method free from the assumption involved in the electrical method. For this purpose an optical method depending upon interference phenomena (Phil. Trans. 1883, p. 652) was employed. Two glass tubes about 16 inches long and ¾ inch in diameter were placed horizontally side by side and were traversed by two interfering beams of light, the interference bands being produced by thick glass plates. The tubes were filled with plane soap films, each tube containing from 40 to 60 films and having its ends closed by pieces of plate-glass. After an hour or more, when the films had thinned sufficiently to appear black, the position of the central interference band in the field was noted, and its displacement when the films were broken, first in one tube and then in the other, carefully measured. From these measurements the average thickness of a black film could be easily deduced, the only assumption made being that the refractive index of the liquid is unaltered by the tenuity of the film. The average thickness of about 900 films was found to be 12·1$\mu\mu$. This result justified the assumption made in the electrical method with regard to the constancy of the specific conductivity of the liquid.

The results established before the recent work was begun were therefore as follows:—(*a*) The thickness of a black soap film formed of a solution containing one part of oleate of soda dissolved in 40 of water with 3 per cent. of KNO_3 added is about twelve micromillimetres. (*b*) It is practically the same when to the soap solution is added two-thirds of its volume of glycerine. (*c*) From this it follows that the specific conductivity of such a solution is the same whether the liquid be considered in large quantity or in the form of a minutely thin film. (*d*) The thickness of the black, though often varying from film to film, is always the same in the same film—*i.e.*, is independent of area and age. With regard to these results it may be said at once that they have all been repeatedly and completely confirmed by subsequent investigation.

We now come to the more recent work. Since in the earlier experiments the solutions were always of the same strength as regards soap, and always contained not less than 3 per cent. of KNO, it was important to determine whether the thickness of a black film is or is not dependent upon the proportion of soap or salt in the solution. The optical method was first employed. The strength of the soap solution being kept constant, viz. 2 grammes of hard soap to 100 cc. of water, the proportion of salt was diminished from 3 per cent. to zero. Under these circumstances, the mean thickness of a black film was found to steadily increase from 12 $\mu\mu$ to about 24 $\mu\mu$. A similar large increase in the thickness was found when the solution contained glycerine, or was made of soft instead of hard soap. When no metallic salt is present, and the strength of the soap solution varies, the thickness of the black increases as the solution becomes more dilute. Thus for a hard soap solution, when the percentage of soap was 3·3, the thickness was found to be 21·6 $\mu\mu$ and rose to 29·3 $\mu\mu$ as the percentage of soap diminished to 1·25. If, on the other hand, the solution contains as much as 3 per cent. of KNO_3, variation in the proportion of soap has little or no influence on the thickness of the black. This is shown by the following table:—

Hard Soap Solution, containing 3 per cent. of KNO_3.

Percentage of soap in the solution	2·5	2·0	1·66	1.14
Mean thickness of the black in $\mu\mu$	13·1	12·1	11·6	12·1

The results above given have been deduced from the optical method of measurement, and the question arises whether the large increase in the thickness of black films formed from an unsalted solution is real, or whether it is due to some incorrect assumption. The only point where error is possible is in the hypothesis that the refractive index is the same as that of the liquid in mass. The thickness of a film varies inversely as $\mu - 1$ (μ being the refractive index), and as the refractive index of the soap solution is 1·34, it would have to be reduced to 1·17 in order that the calculated thickness might be doubled. It appears therefore *à priori* extremely improbable that the mere addition of 3 per cent. of KNO_3 should so completely change the optical properties of the liquid that whereas if the salt be added the refractive index is practically the same in the thin films and in the liquid in mass, yet without the salt the refractive index should be as much as 13 per cent. less than that of the liquid in mass. It may further be mentioned that Drude (*Wied. Ann.* xliii. p. 169, 1891), by an optical method quite different from that employed by us, has compared the refractive indices of black and coloured films, of which the latter may unquestionably be taken as nearly if not quite identical with that of the liquid in mass, and has shown that they do not differ by more than 1 part in 140. Such a variation would not affect the apparent thickness of the films as measured by the optical method by more than 3 per cent., whereas, as we have seen, the presence or absence of the salt alters the apparent thickness by 100 per cent. On the whole, then, the evidence is very strong that the differences of thickness indicated by the optical method are not merely apparent but real, and this point may now be treated as established.

We now pass on to consider the thicknesses of black films as deduced by the electrical method. The method adopted was in all essentials identical with that previously employed and described (Phil. Trans. 1883, pt. ii. p. 645, NATURE, 1883, *loc. cit.*).

The apparent thickness of a black soap film as measured by the electrical method increases as the percentage of added salt diminishes, but in a far larger ratio than would be inferred from the optical method. If the proportion of salt be diminished to zero the thicknesses thus calculated are greater than the greatest thickness at which a film can appear black. Thus with a hard soap solution the apparent thickness rose from 10·6 $\mu\mu$ to 26·5 $\mu\mu$, as the percentage of KNO_3 added was diminished from 3 to 0·5, and became 148 $\mu\mu$ when the solution contained no salt, this number being the mean value derived from fourteen films, the individual thicknesses of which ranged from 79 to 240 $\mu\mu$. In another set of experiments made with a rather stronger soap solution, the apparent mean thickness of the black was 184 $\mu\mu$, the extreme values for six films being 84 and 250 $\mu\mu$. Similar results were derived from a soft soap solution, the mean apparent thickness obtained from the examination of twenty-three black films being 162 $\mu\mu$, and the extremes about the same as before, viz. 80 and 252.

Now a film 148 $\mu\mu$ thick (to take the smallest of the mean thicknesses given above) could not possibly appear black. According to Newton the beginning of the black occurs when the thickness is 36 $\mu\mu$, which is about one-fourth of the smallest mean value obtained from unsalted solutions. We are therefore driven to the conclusion that the close agreement between the results of the optical and electrical methods, which has again and again been proved when the solution contains 3 per cent. of KNO_3 does not hold in the case of unsalted solutions. The measured thicknesses cannot be true thicknesses, and therefore there must be a difference between the specific conductivity of a film, and that of the liquid from which it is formed.

Apart from this, however, is the fact that the apparent thickness varies considerably from film to film, although all the conditions are maintained as far as possible constant. This is certainly due in some cases to a real variation in thickness. We have frequently seen in the same film two different shades of black separated from each other by a definite sharp line, which is generally very irregular in form. The line which separates the black from the coloured part of a cylindrical film thinning in the normal way is always a horizontal circle. This is rarely the case with the boundary between the two black tints. Sometimes a patch of the darker black is completely surrounded by the other, sometimes the line of separation is sinuous, or stands higher at one point than at another. It is thus difficult to obtain comparative measures of the thicknesses of the two tints, as the method of experiment employed assumes the thickness of a cylindrical film to be the same at all points on the same horizontal circle. Such measures, however, as have been made indicate that the thickness of the thicker black is about twice as great as that of the thinner.

The two black tints are not always easy to detect or to distinguish from each other. If only one occurs it is almost impossible to say whether it is the thinner or thicker variety. Frequently the passage of an electrical current through a film, the black portion of which appears to be homogeneous, discloses the existence of the two different tints by producing or intensifying little white flecks which lie along the boundary between the two. On the suppression of the current the flecks become smaller or disappear, but the attention of the observer having been called to the boundary line, there is no difficulty in distinguishing between the regions on the two sides of it, the thinner appearing more intensely black than the other. We have never, when experimenting with solutions containing 3 per cent. of KNO_3, seen any indication of the two shades of black. If the added salt is reduced to 0·5 per cent., the phenomenon is seen occasionally; but with unsalted solutions it is of frequent occurrence. The two varieties of black in a soap film were noticed by Sir Isaac Newton, who remarks that sunlight is reflected from even the darker spots.

But to return to the question of the mean apparent thickness of a black film. As has been stated, the optically measured thickness differs little if at all from the true thickness. If the electrical thickness is approximately equal to the optical thickness, we may assume that the specific conductivity of the liquid is unaltered by the tenuity of the film. If they differ considerably the inference is that the specific conductivity has changed. Now in the case of an unsalted solution containing one part of soap dissolved in sixty of water the optical thickness is 27·7 $\mu\mu$, while the mean apparent electrical resistance is 160 $\mu\mu$. The specific conductivity is therefore greater in the film than in the liquid in mass in the ratio of 5·8 to 1.

A number of experiments have been carried out for the purpose of determining whether the change in the specific conductivity is a function of the thickness of the film, or is peculiar to black films. The result is to show that with an unsalted solution of hard soap the change begins when the film is comparatively thick. Thus, the ratio of the electrical to the optical thickness (which measures the proportional increase of conductivity) is 1·66 when the film exhibits the green of the second order (thickness = 641 $\mu\mu$); it is 1·98 at a thickness of 296 $\mu\mu$, 4·47 at 97 $\mu\mu$ (white of first order) and becomes 5·8 when the film is black.

When the solution contains 3 per cent. of KNO_3 we know that for the black films the conductivity is the same as for the liquid in bulk. That it remains constant under all circumstances is highly probable, though not absolutely certain.

We have now to inquire into the possible causes of the fact that a black film made of an unsalted soap solution appears to be about six times as great as it really is, or, in other words, that the specific conductivity of the film is six times as great as that of the liquid in mass. This increase might possibly be due to (1) evaporation or absorption of water by the film as it thins, (2) changes of temperature, (3) changes in the chemical constitution of the film by the electrolytic action of the current employed, (4) absorption of carbonic acid or of oxygen from the air. In considering these it must be borne in mind that our observations are based on a comparison between two solutions which differ from each other only by the addition to one of them of 3 per cent. of KNO_3. If, therefore, the change in conductivity were ascribed to any one of these causes it would be necessary to assume not only that the cause was competent to produce the change, but that its efficiency was very greatly modified by the addition of the salt. It is extremely improbable that evaporation or absorption of water, changes of temperature, or absorption of carbonic acid (if occurring in the one liquid), would produce the enormous observed change in the conductivity, while they were inoperative in the case of the other. We have not, however, been satisfied with *à priori* considerations, but have experimentally examined each of these possible causes.

With regard to the first, it is sufficient to say that all the precautions which experience has shown to be efficient in securing constancy of composition in the case of *liquide glycérique*—a liquid much more susceptible to changes of composition, due to variations of hygrometric state, than plain soap solutions—have been taken. We may be perfectly sure that the change in conductivity is not due to the loss or gain of water by the film when thinning.

Experiments have been made at various temperatures between 17° and 27° C., but there is nothing in the results obtained to indicate that the apparent thickness of the black either increases or diminishes as the temperature changes. Thus, to take four films out of many that might be selected, we have the following results:—

Temperature	18°·7	21	21°·1	26°·3
Apparent thickness of black film in pipe	171	237	201	135

There is no doubt that the relatively small changes of temperature which occurred in our experiments are not the cause of the large increase in the apparent thickness of a black film.

But the observed result might be due to change in the composition of the liquid caused by the passage of an electric current through the film. The current employed to measure the resistance of the film is always a feeble one; but in order to produce a rapid thinning, we have frequently passed a current from a battery of 28 Leclanché cells down the film from the moment of its formation. Such a current, though probably never exceeding 100 microampères, is passed for a long time, and might conceivably affect the specific conductivity of the liquid. As a specimen of the kind of results obtained, the following, derived from a soft soap solution, may be given. Each of the values of the thickness was obtained from a different film, and the number of cells indicated is that employed to pass a continuous current through the film from its first formation. The measuring current was small and intermittent.

No. of cells.	Apparent thickness of black film, measured electrically, in $\mu\mu$.
0 ...	150 171 148 150
14 ...	155 145 142
28 ...	150 157 179

The conclusion to be drawn from this table was confirmed by experiments in which transient currents from a Ruhmkorff induction coil were employed; they leave no doubt that the passage through a film of such electrical currents as we have used has no appreciable influence on the phenomenon under discussion.

To determine the possible influence of carbonic acid, or of oxygen, absorbed from the surrounding space comparative experiments were made. The apparatus not being air-tight, the plan was adopted of allowing a stream of air carefully freed from CO_2, or of pure oxygen, as the case might be, to flow through the film-box. The results obtained under these conditions, though in some respects not quite satisfactory, justify the assertion that neither the total (or almost total) absence of CO_2 nor a large increase in the quantity of oxygen in the neighbourhood of the film produces any appreciable change in the specific resistance.

It thus appears that a number of possible causes, to which the increase in the conductivity of a thin film might be due, prove on examination to have little or no influence. Although a satisfactory explanation is not at present possible, it will probably be found to depend upon the connection which subsists between the chemical constitution of a film and the surface forces which are brought into play, or are modified by its tenuity. Prof. J. J. Thomson ("Applications of Dynamics to Physics and Chemistry," p. 234) has drawn attention to this connection, and has shown that under certain conditions the chemical action in a thin film throughout which the forces producing capillary phenomena are active, may be totally different from the chemical action in the same substance in bulk. The experiment of Liebreich (*Berlin, Sitzungsberichte*, 1886) is often cited as illustrating this point. When solutions of chloral-hydrate and sodium carbonate are mixed in suitable proportions in a glass tube, chloroform is slowly precipitated as an opaque cloud. Close to the surface, however, and from 1 to 3 mm. below the surface, there is a space perfectly clear and free from chloroform. It is supposed that in this space either the chemical action does not go on, or that if it does chloroform is not deposited. The explanation is not very satisfactory, and in any case the "dead space" is too large to justify us in referring it solely to the action of surface forces. Again, there is no doubt that the surface of a film becomes altered by the action upon it of the surrounding medium, so that the outer layers have different properties from the rest of the liquid. Lord Rayleigh has shown that the surface tension of a soap solution when the surface is new is nearly the same as that of pure water, but diminishes rapidly by exposure to the air. Reinold and Rücker have proved that the surface tension of a cylindrical film is increased by giving the film a new surface (letting fresh liquid flow over it) and that from ten to fifteen minutes elapse before the old value is regained. Other properties of the surface-layer besides its tension may be modified where it is very thin, and the electrical conductivity may be very different from that of the interior liquid. Although the peculiarities of the surface-layer certainly are in some way connected with the main facts here considered, we have shown that they cannot all of them be explained by the simple theory of the formation of a pellicle of different conductivity from the rest of the film.

It is difficult to assign a reason why the addition of salt to the liquid should produce so great a change in the results. In part, the better conducting salt probably masks effects which, when soap alone is used, become predominant; but it is likely that, in part at all events, it actually prevents the changes to which the change in conductivity is due.

The optical method of investigation illustrates the controlling influence of the metallic salt when present in the solution. As we saw above, a small variation in the proportion of dissolved soap has a large effect upon the thickness of the black when no salt is present; but the quantity of soap may be doubled without influencing the thickness, provided the solution contain 3 per cent. of salt.

A. W. REINOLD.

SPONTANEOUS COMBUSTION.[1]

WHEN an inflammable substance ignites or becomes incandescent without the application of fire or other apparent cause, it has been customary to speak of it as spontaneous combustion, a term which I think I shall be able to show you presently does not correctly express the actions which lead to this apparently mysterious result.

Early in the eighteenth century a woman was found burnt to death under circumstances which gave no clue as to the cause of the accident, and in order to satisfactorily explain her death, the theory of spontaneous combustion was devised by the experts of the day, and was generally accepted at a time when little or nothing was known of what takes place during the process which we know as combustion; but as the years rolled on, men's views upon this important subject became wider and more exact, until, in the latter part of the last century, the great French philosopher Lavoisier, partly by his own experiments, and partly by the teachings of the work done by others, gave us a true knowledge of combustion and the changes which take place when a body is burnt, whilst the commencement of this century marked still further the advance of our knowledge in this direction, and also as to the conditions necessary for continuing the combustion or burning of any inflammable substance.

We now know that from the nature of combustion it is impossible for the human body to undergo spontaneous ignition or combustion in the way in which the novelists and scientific experts of the last century believed possible, but there are few amongst us who have not heard of, and even come across, cases in which large masses of coal, small quantities of oily rags, or waste, and hayricks which have been made from grass stacked before it was thoroughly dried, have ignited without any apparent cause, and have kept alive in our minds and on our tongues the term "spontaneous combustion"; and you must pardon me if I commence my lecture this evening by reviewing the teachings of Lavoisier's classical work, and then apply the conclusions we arrive at to those cases of spontaneous combustion which we meet with in our daily work.

The theory of combustion which was generally accepted during the last century, was that every combustible body contained within itself the products of combustion combined with a "something" called phlogiston, and when the substance was burnt, this phlogiston escaped, giving the flame or incandescence of combustion, whilst the products were set free. This theory could not, however, for long stand the test of exact experiment, and as soon as Black introduced the balance into scientific research, it was found that when any substance underwent combustion, the products weighed more than the body before it had been burnt, the reverse of what one would have expected had the phlogistic theory been correct.

During the last century lived Joseph Priestley, one of the most remarkable men this country has ever claimed as her own—a man so varied in his attainments, and so energetic in his life and labour, that he published over one hundred different works dealing with every conceivable subject, from theology to science; but it was in the latter field that he especially shone, and the greatest achievement of his life was the discovery of the gas which we now call oxygen, a discovery which he communicated to his friend Lavoisier.

Lavoisier at once saw the importance of the discovery which Priestley had made, and then conceived and carried out an experiment which has become historical as proving for the first time beyond doubt the fact that the air was not a simple elementary substance, but contained two perfectly distinct gases—oxygen and nitrogen.

Lavoisier placed in a long-necked retort about four ounces of mercury, and so arranged the apparatus that the air above the mercury in the retort should freely communicate with the air in a measured receiver, all contact with the outer air being prevented by standing the receiver in a vessel of mercury. He now heated the four ounces of mercury in the retort nearly to its boiling-point, and kept it at this temperature for twelve days and twelve nights. At first no change took place, some of the mercury merely distilling into the upper part of the apparatus and falling back again; but presently some little red specks began to appear on the surface of the metal, and increased in amount for several days, but at length ceased to form; and after continuing the heating for a day or two longer,

[1] A lecture to working men, delivered by Prof. Vivian B. Lewes at Nottingham, in connection with the British Association

in order to make sure that the action was completed, he allowed the whole apparatus to gradually cool down again to its original temperature.

Before starting the experiment he had carefully measured the air in the apparatus, which amounted to fifty cubic inches, and the first thing which he now noticed was that of this forty-two cubic inches only remained, and that this residual gas had lost all the most characteristic properties of air; a taper plunged into it was at once extinguished, a mouse placed in it died after a few moments; it would, in fact, neither support life nor combustion, and he recognised it as a gas discovered some three years before by Rutherford, and now called nitrogen.

He then collected the red film formed on the surface of the mercury, which weighed forty-five grains, and heated the powder in a hard glass tube to a higher temperature than that at which it had been formed, when it again broke up, leaving behind metallic mercury, and yielding eight cubic inches of a gas which had to an exaggerated extent all the properties which the air had lost—a gas which he at once recognised as being the oxygen or "vital" air which Priestley had discovered in 1774.

It was in this way that the air was shown to consist of the two gases, oxygen and nitrogen, and we know from experience that air is necessary for carrying on those cases of combustion which we ordinarily meet with, and the quickest way to extinguish a fire is to cut off the supply of air from it.

Having reached this point, the next question which suggests itself is, which of the constituents of the atmosphere is it which supports and carries on combustion, and how does it act in doing so? And the answer to these points can most readily be given in Nature's own words, by carefully translating the result of a few simple experiments.

Here are two gas jars, the one containing oxygen, the other nitrogen, and, taking a small ball of tow soaked with turpentine which is burning vigorously, I plunge it into the atmosphere of nitrogen, when it is at once extinguished, but on now relighting it, and plunging it into the oxygen, it burns far more fiercely than before, and emits a most brilliant light. If we continued experimenting in this way, we should find that everything tends to confirm the impression gained from our first experiment, and we soon learn, as Lavoisier did, that anything which will burn in air will burn with still greater vigour in oxygen, whilst nitrogen alone instantly stops the combustion of those bodies which require air to enable them to burn; indeed, we might go a step beyond Lavoisier's experiments, and find that many bodies not looked upon as combustibles, such as iron and zinc, burn with considerable brilliancy in pure oxygen; and it is from these facts that we came to look upon oxygen as our great supporter of combustion.

The enunciation of these truths by the great French philosopher was one of the most important steps in the history of science, but with increase of knowledge we find that we must still further widen our views with regard to combustion, and must take care not to fall into the error of looking upon those substances which will burn in air or oxygen as the only combustibles, and oxygen as the only supporter of combustion; we find, indeed, that these terms are purely relative, and a substance which we look upon as a combustible may, under altered conditions, become a supporter of combustion. Indeed, a body like coal gas, which burns in air or oxygen, will support in turn the combustion of air, and we can experimentally show that it is just as easy to have a flame of air burning in coal gas, as under ordinary conditions to have a flame of coal gas burning in air.

Again, we find that many cases of combustion will take place without the presence of oxygen or those substances generally looked upon as combustibles, and we can take a metal like antimony, and cause it to undergo brilliant combustion by throwing it in a powdered condition into an atmosphere of a gas called chlorine, although neither the metal nor the gas answer to our general ideas as to combustible or supporter of combustion.

If we examine carefully all cases of combustion, we find that in them we have a body with certain definite properties of its own, uniting itself with something else to form what we call the products of combustion, which are equal in weight to the sum of the weights of the two bodies uniting, and which have characteristic properties differing from those of the original substances, an action which we term one of chemical combination; and extended experiments show us that in order to obtain a true conception of combustion, we must look upon it as "the evolution of heat during chemical combination."

The rapidity with which chemical combination takes place varies to a very great extent with surrounding circumstances, and inasmuch as heat is very rapidly dissipated it often happens that where a chemical combination is slow, the heat produced by it is given off as rapidly as it is generated, so that the temperature of the mass becomes but little raised, and escapes detection by our senses. For instance, if I take a steel watch-spring, and having ignited a small piece of German tinder attached to the end of it, plunge it into a vessel of oxygen gas, the combustion of the tinder ignites the watch-spring, which burns away in the gas with the greatest brilliancy, and the evolution of heat is sufficient to fuse some of the metal, the result being that the watch-spring is converted into a chemical compound of iron and oxygen. If instead of bringing about the combination of the iron and oxygen as we have done in a few seconds, we allowed it to remain in moist air for two or three months, combination with the oxygen of the air would result, and the metal would rust away, and if the weight of metal had been the same in each case, and the same weight of oxygen had been combined with, exactly the same amount of heat would have been generated in each case; but in the rapid combustion of the metal, this heat, being all generated in a few seconds of time, would have made its presence perfectly manifest; whilst when the same action is spread over a long period, as in the rusting of the metal, the heat being dissipated as it is generated, escapes our notice; and there are many amongst us who would smile at the idea that the rusting of their garden railings was giving rise to any increase of temperature.

In this case the heat generated by the combination of the iron with oxygen was made manifest by raising the burning metal to a high temperature in the presence of oxygen free from the diluting action of the inert nitrogen which is mixed with it in the air; but we can do the same thing by taking the iron in a very finely-powdered condition, so that a very large surface shall be exposed to the action of the oxygen of the air. I have here iron in this condition, sealed up in a glass tube, and on opening and shaking out the finely-divided metal into the air, it at once enters into combination with oxygen, and the heat generated is sufficient to make it red-hot. If, however, the same weight of iron in a compact form, such as wire, be taken, a long period of time, extending perhaps over years, would be required for its conversion into oxide by air and moisture, and the heat generated would be spread over such a duration of time that it would be inappreciable, unless the conditions were such that the heat was unable to escape or the surface of metal exposed very large. A case of this kind occurred during the manufacture of the Mediterranean telegraph cable, which was enclosed in a strong casing of iron wire, and tightly coiled in water tanks, one hundred and sixty-three miles of cable being wound in a coil thirty feet in diameter. Owing to a leak in the tank which contained the cable the water ran off, leaving the wire casing exposed to air, and the moist metal oxidised so rapidly that sufficient heat was generated to form considerable quantities of vapour, and to give rise to serious fears as to the softening of the insulating material of the core.

Many cases of chemical combination with the oxygen of the air take place in nature, which are so slow that the heat evolved during the action escapes our senses, and indeed all cases of decay are processes of this kind, and the action is termed one of "slow combustion."

A tree left to rot upon the ground gradually disappears in the course of years, being mainly oxidised into gaseous products such as carbon dioxide and water vapour, and yet scarcely any evolution of heat is observed, although the same amount of heat is generated as if the tree had been cut into logs and burnt.

In all cases slow combustion is accelerated by increase of temperature, and the higher the temperature the more rapid becomes the chemical action, and all combustible bodies, at a certain temperature, undergo what is termed "ignition," that is to say, a temperature is reached at which slow combustion passes into ordinary combustion with manifestation of flame or incandescence, the chemical combination being then so rapid that the heat evolved is manifest to our eyesight, whilst a still greater increase in the rapidity of combustion will in some cases bring about the most rapid form of combustion, which we term "explosion."

Many substances are capable of undergoing all three rates of combustion. For instance, it can readily be proved that when organic substances containing hydrogen undergo decay, some of the hydrogen present unites with the oxygen of the air to form water, and the heat generated by the combination is spread over so long a period that at no one moment of time is it perceptible to the sense. If, however, hydrogen gas be confined under pressure in a gas-holder, and allowed to escape through a jet into the air, on being ignited it burns with an intensely hot flame, the heat energy of which can be converted, by suitable contrivances, into other forms of energy, such as mechanical force. In this case as much hydrogen is converted into water in the course of a minute as would have been formed in some years by the process of slow combustion, and the increase in calorific intensity obtained is solely due to the increased rate of combustion, the total thermal value of the hydrogen being the same, whether it is burnt by a slow process taking years, or a rapid one in a minute. If now the same volume of hydrogen be mixed with sufficient air to supply it with the oxygen required to convert it into water, and if a light be applied to the mixture, the hydrogen being side by side with the oxygen necessary for its conversion into water, combustion takes place with enormous rapidity, and the intense heat generated expands the vapour formed to such an extent that an explosion results.

We have now seen that during the decay or slow oxidation of combustible bodies, heat is generated, and that it is only necessary for this heat to reach a certain point, *i.e.* the point of ignition, for the little noticeable slow combustion to become ordinary combustion with its manifestation of flame and incandescence, and it is this action to which the term spontaneous combustion has been given.

When the combustible substance has a great affinity for oxygen, and at the same time a low point of ignition, spontaneous combustion will take place with great ease. Indeed, in some cases, such as that of phosphorus, we are obliged to prevent the access of air to the body if we wish to prevent ignition taking place, and we also find that the finer the state of division of the substance, the more readily will its spontaneous ignition take place, not because dividing the body up in any way lowers the point of ignition, but because the increase in the size of the surface exposed to the oxidising action of the air is so much increased, that the heat is generated with greater rapidity than it can be dissipated. If we take a piece of phosphorus, and expose it to the action of the air, it almost directly commences to give off white fumes, and if the weather is warm, it will in the course of a short space of time even ignite; in cold weather, however, it may be left until it has nearly all undergone slow oxidation without ignition. If, however, we dissolve it in the liquid called bisulphide of carbon, and pour some of this solution upon a piece of blotting-paper or linen, the carbon bisulphide, being highly volatile, will all evaporate, and leave the phosphorus in such a fine state of division that it will at once spontaneously ignite.

In practically all of the cases of spontaneous ignition which come under our notice, we have the heat evolved during the slow combustion kept in by the presence of a mass of non-conducting material, and this heat being unable to escape gradually grows higher and higher, the chemical combination becoming more and more rapid as the temperature increases, until we reach the point at which ignition of the mass takes place.

Sometimes, also, the increase in temperature necessary to bring about spontaneous ignition is partly due to physical actions. If a gas be suddenly compressed heat is always evolved, a fact prettily shown by the so-called fire syringe, in which the heat evolved by the compression of air is sufficient to ignite a piece of German tinder.

Certain bodies have the power of absorbing many times their own volume of gases, and in doing this they not only give rise to a certain increase in temperature, due to the compression of the absorbed gas upon their surfaces or in their pores, but they also increase the chemical activity of the gas so compressed.

Carbon is one of those substances which possess to an extraordinary degree the power of attracting and condensing gases upon their surface, this power varying with the state of division of the particular form of carbon used. The charcoal obtained from dense forms of wood, such as box, exhibits this property to a high degree, one cubic inch of such charcoal absorbing—according to Saussure—

Ammonia gas ...	90	cubic	inches
Sulphuretted hydrogen	55	,,	,,
Carbon monoxide	35	,,	,,
Ethylene—olefiant gas	35	,,	,,
Oxygen	9·25	,,	,,
Nitrogen	6·5	,,	,,

This absorption is very rapid at first, but gradually decreases, and is, moreover, influenced very much by temperature. It is at first purely mechanical, and itself causes a rise of temperature, which in the case of charcoal formed in closed retorts, as in preparing alder, willow, and dogwood charcoal for powder making, would produce spontaneous ignition if it were not placed in sealed cooling vessels for some days before exposure to air. The rate of absorption varies with the amount of surface exposed, and is, therefore, able to take part in this condensing action, so that when charcoal is finely powdered, the exposed surface being much greater, absorption becomes more rapid, and rise of temperature at once takes place. If, after it has been made charcoal, it is kept for a day out of contact with air, and is then ground down into a powder, it will frequently fire after exposure to the air for thirty-six hours, whilst a heap of charcoal powder of one hundred bushels or more will always ignite. It is for this reason that in making the charcoal for powder it is always kept, after burning, for three or four days in air-tight cylinders before picking over, and ten days to a fortnight before it is ground.

There are several very interesting points with regard to the spontaneous combustion of charcoal, which call for more attention than has yet been devoted to it. It is self-evident that the more porous a body is, the greater amount of exposed surface will be available for the condensation of gases, and the great power that charcoal has of absorption is undoubtedly due to its great porosity. Now the temperature at which wood can be carbonised varies very considerably, and wood will begin to char; that is to say, will begin to be converted into charcoal at temperatures very little above that of boiling water, and in the manufacture of some of the newer kinds of gunpowder the charcoal is formed by heating with superheated steam.

Charcoal formed at this low temperature, however, still contains large quantities of hydrogen and hydrocarbons, and is not nearly so porous as charcoal made at a high temperature; and although the diminution in porosity reduces the quantity of oxygen absorbed, yet another cause which tends still more to dangerous rise of temperature comes into play.

When a substance condenses oxygen upon its surface from the atmosphere, the gas is in a very chemically active condition, and will bring about chemical combination with considerable rapidity. For instance, if a piece of platinum foil be heated to redness, so as to drive off all gases from its surface, and be then allowed to cool until it ceases to be visibly red, and is held in a stream of mixed air and coal gas, or air and hydrogen, it again becomes red-hot, owing to the chemical combination of these substances upon its surface; that is to say, it has been able to condense these gases together and set up combustion.

If now charcoal be burnt at a high temperature, the carbon is in a dense condition, and resists to a considerable extent the setting-up of chemical action by the oxygen condensed and absorbed in its pores, but if it has been formed at a low temperature, this condensed oxygen will rapidly act upon the hydrocarbons and hydrogen still remaining in the mass, and will raise in this way the temperature to a dangerous point; and it is more than probable that very many unexplained fires have been brought about by beams and woodwork becoming charred in contact with flues and heating pipes.

It has been experimentally determined that when wood has been charred at 500° it will take fire spontaneously when the temperature is raised in the presence of air to 680°, and that when wood has been carbonised at 260° a temperature of 340° only is required for its spontaneous ignition.

If a beam is in contact during the winter months with a heated flue, or even steam-pipes, it becomes carbonised upon its surface, and during the summer, when the flue or pipe is probably not at work, it absorbs air and moisture, and during the next winter it again becomes heated and further carbonised, whilst the moisture and air are driven out, leaving the pores in a condition eminently adapted for the absorption of more air as soon as the temperature is allowed to fall, and in many cases sufficient heat is generated to cause the charred mass to smoulder and, when air is freely admitted to it, to burst into flame.

In the case of charcoal burnt at a higher temperature, it may be taken that the cause of heating is to a great extent physical, whilst in the low-burnt charcoal it becomes chemical as well as physical, and it is this chemical action which is the most dangerous, and acts in most cases of spontaneous combustion.

The spontaneous ignition of coal has been the cause of an enormous number of serious accidents, and the earliest theory as to its cause was that it was due to the heat given out during the oxidation of the pyrites or "coal brasses," which are compounds of sulphur and iron, and are present in varying quantities in nearly all coal. This idea has held its ground nearly up to the present time, in spite of the researches of Dr. Richters, who twenty years ago showed the explanation was an erroneous one, and even earlier, in 1864, Dr. Percy pointed out that the cause of spontaneous ignition was probably the oxidation of the coal, and that the pyrites had but little to do with it. Pyrites is found in coal in several different forms, sometimes as a dark powder closely resembling coal itself, and in larger quantities in thin golden-looking layers in the cleavage of the coal, whilst sometimes again it is found in masses and veins of considerable size; these masses, however, are very heavy and are carefully picked out from the coal, and utilised in various manufactures. The yellow pyrites, and even the dark varieties, when in the crystalline form, remain practically unaltered, even after long exposure to moist air, but the amorphous and finely divided portions will oxidise and effloresce with great rapidity, and it is during this oxidation that the heat is supposed to be generated.

Some coals that are very liable to spontaneous ignition only contain 0·8 per cent. of pyrites, and if we imagine this to be concentrated in one spot instead of being spread over the whole mass, and to be oxidised in a few hours, the temperature would rise only a few degrees, and under ordinary circumstances this rise in temperature would be practically inappreciable.

The oxidisation of masses of pyrites under certain conditions gives rise to the formation of ferrous sulphate and sulphur dioxide, with liberation of sulphur, and one might easily imagine that this free sulphur, which has an igniting point of 250° C., would play an important part in the action by lowering the point of ignition. This, however, could only happen with large masses of pyrites undergoing oxidation, and with the small amount of pyrites present in coal, supposing air were present in sufficient quantity to oxidise it, the sulphur formed would be converted into sulphur dioxide at temperatures as low as 60° C. This oxidation of sulphur at low temperatures is an action not generally known, but in my experiments I have found it takes place with considerable rapidity. The only way in which pyrites can assist the spontaneous ignition of coal is that when it oxidises, it swells and splits up the coal, thus exposing fresh surfaces to the action of the atmospheric oxygen.

I have carefully determined the igniting points of several kinds of coal, and find that

Cannel coal	ignites at	698° F.	= 370° C.
Hartlepool coal	,, ,,	766° F.	= 408° C.
Lignite coal	,, ,,	842° F.	= 450° C.
Welsh steam coal	,, ,,	870° F.	= 477° C.

So that it is impossible for the small trace of pyrites scattered through a large mass of coal, and slowly undergoing oxidation, to raise the temperature to the necessary degree.

When coal is heating, a distinctive and penetrating odour is evolved, which is the same as that noticed when wood is scorched, and the gases produced consist of nitrogen, water vapour, carbon dioxide, carbon monoxide, hydrocarbons of the paraffin series, and sulphuretted hydrogen, the presence of the latter gas showing beyond doubt that oxidation of the sulphur has nothing to do with the action.

Ever since coal has been generally adopted as a fuel, it has been recognised that great care was necessary in the storing and shipment of masses exceeding 1000 tons, and if the coal has been stored wet or in a broken state, firing or heating of the mass has frequently taken place. Much inconvenience and loss has been caused by this on shore, but the real danger has occurred during shipment, and owing to this many a vessel has been lost with all hands, without any record of the calamity reaching shore.

Owing to the greater facility for treating the coal when it becomes heated on shore in coal stores and gas works, absolute ignition only rarely takes place, and it is mainly from evidence obtained in the case of coal cargoes that we learn most as to the causes which lead to it.

Coal is a substance of purely vegetable origin, formed out of contact with air, by long exposure to heat and pressure, from the woody fibre and resinous constituents of a monster vegetation which flourished long before the earth was inhabited by man. Coal therefore may be looked upon as a form of charcoal, which having been formed at a temperature lower than that of the charcoal-burner's heap, and under great pressure, is very dense, and still contains a quantity of these constituents which, in the ordinary burning, are driven off as wood naphtha, tar, &c., and these bodies consist of compounds containing essentially carbon and hydrogen, together with a little oxygen and nitrogen, and form the volatile matter and hydrocarbons of the coal. Coal also contains, besides these, certain mineral bodies, which were present in the fibre and sap of the original wood, and these form the ash which is left behind on the coal being burnt. These mineral substances consist almost entirely of gypsum or sulphate of lime, silica, and alumina, together with some oxide of iron, which gives the colour to the reddish-brown ash of many coals, and which has been formed by the decomposition of the pyrites in the original coal.

The mineral constituents of coal are the only ones, with the exception of the pyrites, that play no part in the phenomena attending the heating and spontaneous ignition of coal, and we need therefore only regard the actions which take place when the carbon, hydrocarbons, and pyrites in freshly-won coal come in contact with air and moisture.

Certain kinds of coal exhibit the same power of absorbing gases which charcoal has, although to a less degree. The absorptive power of new coal due to this surface attraction varies, but the least absorbent will take up one and a-quarter times its own volume of oxygen, whilst in some coal more than three times their volume of the gas is absorbed, which gives rise to an increase in temperature, and tends to increase the rate of the action which is going on, but is rarely sufficient to bring about spontaneous ignition, as only about one-third the amount of oxygen being absorbed by coal that is taken up by charcoal, and the action being much slower, tends to prevent the temperature reaching the high ignition point of the coal.

All coal contains a certain proportion of hydrogen, with which some of the carbon is combined, together with the nitrogen and oxygen, forming the volatile matter in the coal. The amount of this volatile matter varies greatly, anthracite containing the smallest quantity, and cannel and shale the largest. When the carbon of the coal absorbs oxygen, the compressed gas becomes chemically very active, and soon commences to combine with the carbon and hydrogen of the bituminous portions, converting them into carbon dioxide and water vapour. As the temperature rises so this chemical activity increases, so that the heat generated by the absorption of the oxygen causes it to rapidly enter into chemical combination. This kind of chemical combination—oxidation—is always accompanied by heat, and this further rise of temperature helps the rapidity of oxidation, so that the temperature rises steadily; and this taking place in a large mass of coal, which from physical causes is an admirable non-conductor, will often cause such heating of the mass that if sufficient air can pass into the heap in order to continue the action the igniting point of the coal will be reached.

It has been suggested that very bituminous coal, such as cannel and shale, are liable to spontaneous ignition from the fact that heavy oils would exude from them on a rise of temperature, and that these, by oxidising, might produce rapid heating. Experiment, however, shows that this is not the case, and that the heavy mineral oils have a decided effect in retarding heating.

We can now trace the actions which culminate in ignition. As soon as the coal is brought to bank, absorption of oxygen commences, but except under rare conditions the coal does not heat to any great extent, as the exposed surface is comparatively small, and the largeness of the masses allows of the air having free access to all parts, so keeping down the temperature. After the coal has been screened and the large pieces of pyrites picked out, it is put in trucks. Here it begins to get broken up, owing to the many joltings and shuntings, and so offers a larger surface to the action of the air. When it has arrived at the ship, it is further broken up by being shot down the tips or shoots, and more harm is done at this than at any other period, for the coal is broken by reason of the distance it has to fall, and it has to bear the impact of every succeeding load falling upon it, and it rapidly becomes slack, so that the under part of the ship-load is a dense mass of small coal, which soon rises in temperature by reason of the large surface exposed to the air and the consequent absorption of oxygen. This sets up chemical combination between the oxygen absorbed by the coal and the hydrocarbons, and in some cases culminates in combustion.

It is found that the mass of coal exercises a most important action in the liability to spontaneous combustion, as although with 500 tons of coal to the cargo the cases of spontaneous combustion amount to only about ¼ per cent. when the bulk is increased to 2000 tons, cases of spontaneous combustion rise to 9 per cent., this being due to the fact that the larger the cargo the more non-conducting material will there be to keep in the heat, and also to the fact that the breaking-up of the coal and the exposing fresh surfaces will of course increase with increase in mass; and it is also found that coal cargoes sent to European ports rarely undergo spontaneous combustion, whilst the number of cases rise to a startling extent in shipments made to Asia, Africa, and America. The result is party due to the length of time the cargo is in the vessel, the absorption and oxidation being a comparatively slow process, but the main cause is the increase of heat in the tropics, which causes the action to become more rapid; and if statistics had been taken, most of the ships would have been found to have developed active combustion somewhere about the neighbourhood of the Cape, the action fostered in the tropics having raised the temperature to the igniting point by that time.

Moisture has a most remarkable effect upon the spontaneous ignition of coal. The absorption of oxygen is at first retarded by external wetting, but after a time the presence of moisture accelerates the action of the absorbed oxygen upon the coal, and so causes a serious increase of heat. The researches of Cowper, Baker, Dixon, and others, have of late years so fully shown the important part which moisture plays in actions of this kind, that it is now recognised as a most important factor. A very marked case of the influence of moisture came under my notice a few months ago. A ship took in a cargo of coal at a South Welsh port, the weather being fine and dry whilst she was loading at the main hatch, but wet whilst she was taking in the coal at the after-hatch, the result being that the temperature in a few days was uniformly about 10° higher in the coal that had been loaded wet, than in the dry portion of the cargo, spontaneous ignition being the final result at the after-hatch.

In order to prevent the spontaneous ignition of large masses of coal, it is manifest that every precaution should be taken during loading or storing to prevent crushing of the coal, and on no account must a large accumulation of small coal be allowed. Where possible the depth of coal in the store should not exceed 6 to 8 feet, and under no conditions must steam-pipes or flues be allowed so near the mass of coal as to give rise to any increase of temperature. These precautions would amply suffice to prevent spontaneous ignition in stored coal on land, whilst special precautions would have to be taken in the case of coal for shipment.

Perhaps the commonest case of spontaneous combustion is the ignition of oily waste or greasy cotton rags. Nearly all vegetable and animal oils have the power of slowly absorbing oxygen, and in some of them this goes on with considerable rapidity, with conversion of the oil into a resin, a property which gives them the power of drying, and causes a considerable rise of temperature. A mass of oil, however, only exposes a very small surface to the oxidising influence of the air, but when such oil comes to be spread upon any non-conducting fabric, the oxidisation is very rapid, and the non-conducting power of the fibre of the fabric prevents the rapid dispersion of the heat, with the result that even a small quantity of such oily substance will readily inflame.

There are plenty of well-authenticated cases in which even a handful of oily cotton waste, which has been used for polishing furniture, has ignited when thrown on one side, and caused most disastrous fires. Just twenty years ago Mr. Galletly read a most valuable paper before the Chemical Section of the British Association, in which he showed that the liability of oils to produce spontaneous combustion was in proportion to their tendency to dry. If a substance like cotton-waste be rendered oily with anything except the mineral oils, it acquires the power of taking up oxygen from the air, and this gives rise to heat. The oxidation is slow at ordinary temperatures, and accordingly it may be some time before the increase of temperature becomes manifest; but when this point is reached, the action proceeds with great rapidity, and the point of ignition is reached in a very short time, and then the mass bursts into flame. If the oily matter be placed in a warm position at first, spontaneous ignition may take place within a few hours, or even minutes. Galletly found that oily cotton at ordinary temperatures took some days to heat and ignite, whilst if placed in a chamber warmed to 130° to 170° F. (54° to 76° C.) the cotton greasy with boiled linseed ignited in 1 hour 15 minutes, and olive oil on cotton in 5 hours; and in a chamber heated to 180° to 200° F. (82° to 93° C.) olive oil on cotton ignited in two hours.

Cases of spontaneous combustion, due to this cause, have been more abundant than from any other, and cases are even on record where serious fires have resulted from sparrows using oily waste in the construction of their nests. In all well-regulated workshops the orders against allowing any accumulation of oily waste are very stringent, and the most reasonable precaution to be taken is that all oily material, when done with, should be thrown into a metal vessel containing water, or which, at any rate, can be either emptied of waste or filled with water at night. If a sheet of cotton be hanging in a warm room and is splashed with oil, a hole will often be found charred in the fabric by the next morning, whilst if a few drops of a drying oil be allowed to fall on powdered charcoal or lamp-black, ignition is almost certain to follow in a few hours.

Another common case of spontaneous ignition is that of haystacks which have been made up before the grass has been thoroughly dried, this being due to the sap left in the vegetable fibre undergoing fermentation, which being a process of oxidation gives rise to heat. This heat is kept in by the surrounding hay, which is an admirable non-conductor of heat, and gradually increases until the ignition point of the mass is reached, when the stack bursts into flame. In some cases the action does not go as far as this, and we often see the inside of a haystack charred to an almost black colour, showing that the action has stopped but little short of the point required to give active combustion, this being probably due to the stack having been very closely built, and the access of air to the centre being small, and in some cases, when such a rick is cut, the air coming in contact with the central portion causes active ignition. If hay has once been properly dried, and then becomes wetted with rain, spontaneous ignition hardly ever takes place, although the hay becomes mouldy, and it is evident that the action which leads to ignition of the hay is fermentation of the sap.

Having now discussed the more common cases of spontaneous ignition, and seen that in every case it is due to rise of temperature, brought about by chemical action until the igniting point of the substance is reached, we are in a position to understand the impossibility of spontaneous combustion taking place in the human body.

The process of respiration by which the tissues of the body used up in every action, voluntary or involuntary, are got rid of by a process of slow combustion, gives a normal temperature to the living body, and it might seem, at first sight, possible by preventing the escape of such temperature, to increase it to a point at which ignition might be possible; but we know by experience that the effect of swathing the body in non-conducting materials, so as to prevent the escape of heat from it, results in profuse perspiration, and before the living flesh could undergo combustion it would be necessary to drive from it the whole of the moisture which it contains.

The human body contains from 75 to 80 per cent. of its weight of water, and in order to evaporate this amount, an enormous amount of heat would be required, and life would have been impossible long before the necessary dryness of the mass had been arrived at. In fact, the moisture present in the body may be looked upon as its great safeguard against the effect of heat, and it is perfectly possible for a living man to remain in an oven which would roast a steak or cook an egg; the evaporation of water from the skin taking up so much heat that the temperature of the living flesh would never rise above a certain point until the moisture was exhausted. It used to be supposed that the cases of spontaneous combustion took place in people whose intemperate habits had caused the body to become saturated with alcohol, and that it was this substance which caused its ready ignition; but as Liebig pointed out, some forty years ago, the presence of the alcohol could have no effect, as if we take a sponge and soak it in spirits of wine and ignite it, the alcohol burns away and leaves the sponge untouched, and the same thing would undoubtedly happen in the case of the living flesh.

In this lecture I have tried to bring before you the important fact that spontaneous combustion merely means that the heat due to chemical actions taking place in any substance, heat which has been unable to escape has raised the temperature to the point of ignition, a point at which slow combustion passes into rapid combustion with manifestation of incandescence; and in speaking of spontaneous combustion, we must clearly remember that it represents merely the acceleration of an action which has been going on slowly and surely, although our senses may have been too deadened to detect it, and that if we wished to be hyper-critical, "Unaided Ignition," or "Natural Ignition," would be a far more correct term to apply to it than "Spontaneous Combustion."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following appointments in connection with the scientific departments are announced:—Mr. Francis Darwin, Reader in Botany, to be Deputy Professor in the place of Prof. Babington, who is still unable to lecture; Dr. D. MacAlister to be Assessor to the Regius Professor of Physics; Dr. Hill, Master of Downing, and Dr. H. D. Rolleston to be Examiners in Anatomy; Dr. A. S. Lea and Prof. Schäfer to be Examiners in Physiology; Dr. W. J. Sollas and Mr. P. Lake (St. John's) to be Examiners in Geology; Mr. Skinner (Christ's) to be an Examiner in Chemistry; Prof. J. J. Thomson and Prof. G. F. Fitzgerald (of Dublin) to be Examiners in Physics; Mr. A. Sedgwick (Trinity) and Mr. W. Bateson (St. John's) to be Examiners in Zoology; Prof. Lewis and Mr. H. A. Miers to be Examiners in Mineralogy; Mr. Seward (St. John's) and Prof. D. E. Oliver to be Examiners in Botany.

Prof. Sir R. S. Ball has been appointed an Elector to the Isaac Newton Astronomy Studentships.

The Moderators and Examiners for the next Mathematical Tripos (Part I.) are Mr. Walsh (Jesus), Mr. Dawson (Christ's), Mr. Burnside (Pembroke), and Mr. Whitehead (Trinity). For the Second Part, Dr. Forsyth, Sir R. S. Ball, Prof. Lamb, and Mr. H. F. Baker (St. John's) are to examine.

Mrs. E. J. Moore, daughter of the late Colonel Fletcher, has presented to the University her father's valuable collection of Silurian fossils, in supplement of the Fletcher collection purchased many years ago for the Woodwardian Museum.

The Clerk Maxwell Studentship in Experimental Physics, of the value of about £180 a year, tenable for three years, is vacant by the resignation of Mr. W. Cassie, who has been appointed to a professorship at the Royal Holloway College. Candidates must be members of the University who have been a student for one term or more at the Cavendish Laboratory. The names of applicants are to be sent to Prof. J. J. Thomson before November 18.

A grant of £100 from the Worts Travelling Scholars Fund has been made to F. W. Keeble, Frank Smart student of Caius College, to enable him to pursue botanical research in Ceylon.

An examination for scholarships and exhibitions in Natural Science, of the value of £80 a year and under, will be held at Trinity College on Tuesday, October 31.

AT the annual meeting of the New Decimal Association, on October 18, Mr. Samuel Montagu, M.P., remarked that there was a prospect of the United States adopting the metric system as well as a decimal system of coinage. Efforts had been made to induce Mr. Acland to instruct inspectors to examine in the metric system in those schools where it was taught, and, in a letter received from the Education Department on the subject, it was said: "The Code does not prescribe knowledge of the metric system, but of the principles of that system—*i.e.* of the diminution of quantities by tenths, and their increase by tens, with examples sufficient to illustrate the conveniences of the system. Her Majesty's inspectors are required to satisfy themselves that the principles as thus defined are properly taught. It is proposed to issue a memorandum to inspectors on the point at an early date."

SCIENTIFIC SERIALS.

American Journal of Science, October.—On endothermic reactions effected by mechanical force, by M. Carey Lea. The object of this investigation was to find whether the blackening effects of pressure upon the silver haloids and other salts could be made immediately visible to the eye, instead of after the application of a reducing agent. For this purpose the pressure was increased to about a million pounds per square inch, or about seventy thousand atmospheres. This pressure was obtained by means of a vice actuated by a screw with six turns to the inch and a lever three feet long. The nuts had to be four inches in length to prevent stripping of the thread. The jaws were specially constructed, and faced with steel welded on. The materials experimented upon were wrapped in platinum or silver foil, which remained unaffected by the pressure. Silver sulphite and carbonate were moderately darkened by two days' pressure, and silver salicylate considerably so. Salts of mercury also showed pronounced effects, which prove that mechanical force can bring about endothermic reactions corresponding to those affected by light, heat, and other forms of energy.—Conditions of Appalachian faulting, by Bailey Willis and C. Willard Hayes. The authors discuss the antecedent conditions for the development, the mechanics of step-folds and thrust-faults as bearing upon actually observed Appalachian structure, and the direction from which the compressing force acted. They come to the conclusion that the latter was equal in opposite directions, and directed north-westward and south-eastward.—On the separation of copper from cadmium by the iodide method, by Philipp E. Browning. The copper was precipitated from a mixed solution by potassium iodide, and filtered through an asbestos felt, washed, dried at 120° C. and weighed. The filtrate and washings containing the cadmium were heated to boiling, and sufficient sodium carbonate was added to complete the precipitation. The precipitate was washed with hot water until free from sulphate or iodide. The crucible containing the cadmium carbonate was heated gently at first, then gradually to a higher degree until the white carbonate had changed to the brown oxide. The method, as tested by means of standard solutions, is fairly accurate, and it is simple in manipulation.—Also papers by Messrs. Foerste, Hidden, Wheeler, Eakins, Williams, Penfield, and Marsh.

THE *American Meteorological Journal* for October contains an account, by A. L. Rotch, of the establishment of a meteorological station at Charchani, near Arequipa, at an altitude of 16,650 feet, which is said to be the highest station in the world. A sum of money was left to Harvard College Observatory by U. A. Boyden, for the purpose of establishing an observatory at a high station, and owing to the remarkable clearness of the air at Arequipa, Peru, this situation was selected for the purpose. The establishment is fully equipped with instruments and is 8,050 feet above the sea; to the north east and ten miles distant is the quiescent volcano of the Misti, 19,000 feet in altitude, and twelve miles north rises Charchani, 20,000 feet high. The meteorological station now in question has been established just below the permanent snow line, and is supplied with self-recording aneroid and thermometers. The ascent from the permanent observatory, 8,600 feet below, can be made by mule in about eight hours, and an assistant is entrusted with the duty of visiting the station periodically to attend to the records. The results of the observations at both stations will be published in the Annals of the Harvard College Observatory, and will furnish a valuable addition to our knowledge of mountain meteorology.

In the same number, Prof. G. E. Curtis gives an analysis of the causes of rainfall, with especial relations to surface conditions. Among these a principal question is whether forestation increases and deforestation decreases the rainfall. The author considers that the influence of forests has been over-estimated, and that if they affect the rainfall, the amount has, in most cases, not been greater than the amount of probable error in the observations themselves, and therefore that the statistics give no assurance that the effect is not an error of observation. If the rainfall is increased it must be due either to an increase of evaporation, and its subsequent precipitation over the same region, or to the diversion of rain to the forest area, which might have fallen elsewhere.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 16.—M. Lœwy in the chair.—On the stability of equilibrium of the axis of the gyroscopic top, by M. H. Resal.—On the partial differential equation presented in the theory of the vibrations of a membrane, by Émile Picard.—On the crystallisation of water by decompression below zero, by M. E. H. Amagat. The experiments were performed with the apparatus provided with glass sights used for studying the solidification of liquids under pressure. But the conical sights mounted in ivory were apt to split into plates, and lose their transparency under high pressures. Cylindrical pieces mounted with marine glue were substituted, some of which resisted pressures up to 1800 atmospheres. The water enclosed in the steel cylinder was first solidified and maintained at a temperature below zero. By gradually raising the pressure, the ice was fused and made to disappear completely. On diminishing the pressure, crystals were deposited on the inner surface of the glass, just as in the case of bodies denser in the solid state when the pressure was raised. The phenomenon is, however, rather more difficult to produce. The solidification was especially retarded when care was taken to fuse all the crystals by pressure, but even when a few fragments were left no such beautiful crystals were obtained as in the case of chloride of carbon. It would be extremely interesting to follow up, for a certain number of liquids, the variation of the point of fusion under very high pressures; as the ratio of the coefficients of compressibility of water and of ice is unknown, it may be asked whether under sufficient pressures the density of ice does not exceed that of water, thus giving rise to a point of inversion which would assimilate the behaviour of water to that of other liquids, or whether other liquids show such a point of inversion in the opposite sense. This would explain certain appearances observed in the case of chloride of carbon.—On an extension of Riemann's method applied to equations of the second order to equations of any order, by M. Delassus.—On the third principle of energetics, by M. H. Le Chatelier. This is a reply to M. Meyerhoffer's criticism, and shows that the term capacity for energy is differently defined by the two authors. Thermodynamic theory is based upon two experimental principles and an hypothesis concerning the nature of heat. The latter may be eliminated by substituting for it the experimental principle which can be expressed as follows: It is impossible to extract energy from a system of bodies without making two at least of its constituents experience changes of opposite sense. From this the proportionality of work performed and heat consumed or generated is easily deduced. It is this proportionality which enables us to reduce the number of algebraic equations to two, sufficient to represent three distinct experimental principles.—On the electric conveyance of heat, by M. L. Houllevigue. The difference of potential between a conductor and iron is different accordingly as the iron is magnetised or not. One joint of a copper-iron couple was brought into a magnetic field, and the other left out. Since this arrangement could not give rise to a steady current without creating energy, an opposing electromotive force was to be expected between the variously magnetised parts of the iron. Such a difference of potential was, in fact, found, the balance being in favour of the less magnetised portions.—On some properties of the oxides of lead, by M. A. Bonnet.—On the interior temperature of bread coming out of the oven, by M. Balland. Experiments performed on various kinds of bread from different ovens show that the temperature of the crumb during baking reaches 100° or 102°, that of the crust being much higher. When beyond 100° the steam imprisoned by the crust is under a certain pressure. If this pressure is relaxed by the bursting of the crust, the temperature of the interior falls to 100°.—Observations of the phenomena of karyokinesis in the blastoderm cellules of the teleostea, by MM. E. Bataillon and R. Kœhler.—On the germination of the Ricinus, by M. Leclerc du Sablon.—A new enemy of the vine, *Blanyulus guttulatus*, Fabr., by M. Fontaine. This is a myriapod which invades the buds in numbers, ranging from five to ten per bud, forming balls of the size of a small pea. Washing with potassium sulphocarbonate and sulphuring the soil are remedies proposed.—On some phenomena relating to the movement of the sea near Bonifacio, by M. Nicol.

DIARY OF SOCIETIES.

London.

THURSDAY, October 26.

Institution of Mechanical Engineers, at 7.30.—On the Working of Steam Pumps on the Russian South-Western Railways: Alexander Borodin.

FRIDAY, October 27.

Physical Society, at 5.—On Air-Core Transformers: E. C. Rimington.—Two Experiments on the Rings and Brushes in Crystals, and Electrical Radiation in Copper Filings: W. B. Croft.

SUNDAY, October 29.

Sunday Lecture Society, at 4.—Savages and Barbarians: a Sketch of their Institutions and their Growth from Savagery to Barbarism: Prince Kropotkin.

THURSDAY, November 2.

Linnean Society, at 8.—A Contribution to the Phanerogamic Flora of Mato Grosso and the Northern Chaco: Spencer Le Marchant Moore.—On a New Freshwater Schizopod from Tasmania: G. N. Thomson.

FRIDAY, November 3.

Geologists' Association, at 8.—*Conversazione.*

BOOKS RECEIVED.

Books.—Plane Trigonometry: S. L. Loney (Camb. Univ. Press).—The Mummy: Dr. E. A. W. Budge (Camb. Univ. Press).—With the Woodlanders and by the Tide: a Son of the Marshes (Blackwood).—Romance of Low Life amongst Plants: Dr. M. C. Cooke (S.P.C.K.).—Eleventh Annual Report of the U.S. Geological Survey, Part i: Geology.—Eleventh Annual Report of the U.S. Geological Survey, Part ii.: Irrigation: J. W. Powell (Washington).—Measurement of Light and Colour-Sensations: J. W. Lovibond (Gill).—Results of Astronomical Observations made at Sydney Observatory, N.S.W. in the years 1879, 1880, and 1881: H. C. Russell (Sydney, Potter).—Horns and Hoofs, or Chapters on Hoofed Animals: R. Lyddeker (H. Cox).—The Municipal Technical School and School of Art, Manchester, Session 1893-94, Syllabus (Manchester).—Round the Works of our Principal Railways (Arnold).
